USS data traffic is also handled differently depending on whether a 3270-format or SCS-format USS table is used. If a 3270-format USS table is used with a TN3270E connection that has negotiated BIND-IMAGE, a Telnet-generated Bind/Unbind encapsulates the USS traffic. If the connection is TN3270, BIND-IMAGE is not negotiated, or the SCS-format USS table is used, Telnet does not encapsulate the USS traffic in a Bind/Unbind. If a 3270-format USS table is used, the Telnet data type for all traffic is 3270-DATA. If an SCS-format USS table is used, the Telnet data type for all traffic is SSCP-LU-DATA. Regardless of USS table format, if the SYSREQ function is supported on a TN3270E connection and SYSREQ is received by Telnet, Telnet will accept a LOGOFF command in SSCP-LU-DATA format. If the client sends any command other than LOGOFF, COMMAND UNRECOGNIZED is returned in SSCP-LU-DATA format. If the client sends a second SYSREQ, Telnet reverts back to whatever the session state was prior to receiving the first SYSREQ.

USSCMD parsing also includes checking for INTERPRET table entries that might provide more function than USS tables alone can provide. Sample USS tables are in TCP/IP data sets SEZAINST(EZBTPUST) and SEZAINST(EZBTPSCS). A sample INTERPRET table is in TCP/IP data set SEZAINST(EZBTPINT). The 3270 format USS sample has been assembled, linked, and loaded into the product data set. The tables can be used by coding the USSTCP and INTERPTCP mapping statements in BEGINVTAM. For example, the
statements below will map the sample tables to the client at IP address 1.1.1.1. See “Mapping Objects to Client Identifiers” on page 578 for mapping details.

<table>
<thead>
<tr>
<th>USSTCP</th>
<th>EZBTPUST, EZBTPSCS</th>
<th>1.1.1.1</th>
</tr>
</thead>
<tbody>
<tr>
<td>INTERPTCP</td>
<td>EZBTPINT</td>
<td>1.1.1.1</td>
</tr>
</tbody>
</table>

A new table can be created at any time and link-edited. Customized USS and INTERPRET tables can be created to change messages, commands, and translation tables. For example, messages can be changed to have non-English text or to have different syntax. Commands can be changed to accept different syntax or to have different default values. A VARY TCPIP,tnproc,OBEYFILE command will cause Telnet to load the new table with the new profile being processed. Any new connection using the new profile will be assigned the new table. Telnet also supports dynamic updating of same-name USS or INTERPRET tables. The VARY TCPIP,tnproc,OBEYFILE command adds the new version of the table to the new profile. New connections use the new copy associated with the new profile while old connections continue to use the old copy associated with the old profile.

**USS table customization**

Customized USS tables are used by both VTAM and Telnet, with any product-specific character substitutions converted to blanks. For example, @@SSCPNM is blank for Telnet and @@PRT is blank for VTAM. Telnet USS processing also supports system symbolic substitution. VTAM does no substitution for system symbolics. The tables must be in a data set that is in the system's linklist or is in the STEPLIB statement of the TCP/IP startup procedure. Any changes to a Telnet USS table should be made with supplementary user-defined USS tables. The IBM-supplied USS table should not be changed as it provides a good example of coding most commands and messages. Telnet loads the first table that is found with the name EZBTPUST and defines it as the default USS table. If this table is not found, there is no default USS table. Whether to include a default USS table depends on the wanted message output. When writing a USS Message, Telnet searches the USS table that is mapped to the client first. If the message does not exist in the mapped table, Telnet searches the default table. If the message does not exist in the default table, Telnet writes USMSGS14. If no default table exists, Telnet generates a USMSGS14. For 3270 format USMSGS, the user can get back to the USMSGS10 from any message by pressing the CLEAR key. The default table does not affect the USS commands. The command entered must be in the mapped table or it is not recognized. The sample SCS USS table found in SEZAINST(EZBTPSCS) is not assembled and linked, and it is not loaded into Telnet as a default SCS USS table. The table must be assembled, linked, loaded, and mapped in the Telnet profile to be used.

**Creating a USS table**

The following macro instructions are used to create the USS table. Telnet USS function supports almost all VTAM session-level USS message and command definitions. See z/OS Communications Server: IP Configuration Reference for macro details.

- **USSTAB** indicates the beginning of the USS table.
- **USSCMD** defines commands accepted by Telnet.
- **USSPARM** defines each operand or positional parameter that can be specified on the USSCMD macro instruction. It also defines default values for the operand or positional parameter. Multiple USSPARM macro instructions can be associated with a USSCMD macro instruction. For each operand or positional parameter code a USSPARM macro instruction.
- **USMSGS** defines messages sent from Telnet.
- **USSEND** indicates the end of the USS table.

The following rules are some of the more common rules to consider when you are coding a new USS table. Also, see the samples in SEZAINST(EZBTPUST) and SEZAINST(EZBTPSCS) as a guide. “Considerations when using mixed-case passwords” on page 619 describes general table rules.

- If a DEFAULTAPPL application is mapped at the same Client Identifier level as a USS table, or an LUMAP-DEFAPPL application is mapped, the USS table is used only to return error messages and optionally after the first session logoff. FIRSTONLY or LOGAPPL options on DEFAULTAPPL will cause Telnet to send a USMSGS10 after the first session logoff. DEFAULTAPPL without the FIRSTONLY or LOGAPPL options will cause Telnet to request a session with the default application after every session logoff.
• Both the 3270 data stream and the SNA character stream (SCS) formats are supported. For more information, see 3270 Data Stream Programmer’s Reference and the table samples.
• If a user-defined table is coded as part of another module, code an assembler EXTRN definition statement for the table name in that module so the table will be known externally and can be accessed by other modules.

Below are message related rules.
• 3270 format USSMSGs must contain the 3270 data stream write control characters (WCCs).
• All character substitutions (@@’s) substitute the same number of characters. Any character substitution that is VTAM-specific will be translated to blanks. If the substituted value is smaller, the field is padded to the right with blanks. The parameter LUNAME or SCAN must be coded on the USSMSG macro instruction for Telnet to perform character substitutions. For a complete list of character substitutions, see z/OS Communications Server: IP Configuration Reference for Telnet and z/OS Communications Server: SNA Resource Definition Reference for VTAM. Telnet supports multiple USSPARMs with the DATA keyword. This method can be used to pass multiple data parameters to the host application. For example, two DATA USSPARMs allow the user to type 'TSO USER1 PROC001' and have both the user ID and the ProName passed to TSO as data. Telnet also supports the system symbolic substitution, padding the right when the substituted value is smaller than the symbolic. VTAM USS processing does not support system symbolic substitution.

Below are command related rules.
• LOGON command format
  PL1 - logon applid(tso) logmode(snx32702) data(user1)
  BAL - logon applid=tso,logmode=snx32702,data=user1
• Any application defined in a USSCMD macro instruction must also be specified on either an ALLOWAPPL or a RESTRICTAPPL statement in the Telnet profile.
• If the USS Command rules in z/OS Communications Server: IP Configuration Reference cannot be followed, use an interpret table to convert the character-coded command into a formatted SNA request.

Considerations when using mixed-case passwords
Mixed-case passwords can be used by applications if an SAF-compliant security product (such as RACF) has enabled this support. In some cases, the USS LOGON DATA parameter is used to send the password to the application. If a terminal user enters a mixed-case password on the USS LOGON command and it is translated to uppercase by the translation table, the logon will fail if the target application expects the password in mixed case.

The USS LOGON command is displayed on the terminal as it is typed, so the password is displayed unless the 3270 format is used and the password is entered into a field with a non-display attribute. For additional security, inform the terminal user to stop entering the password as part of the USS LOGON. Instead, the application should prompt the terminal user for the password in a non-displayed field. If mixed-case passwords are used and the terminal user continues to enter the password as part of the USS LOGON command, the logon will fail when using TRANSLATE=YES (the default) on the USSPARM, because the password has been translated to uppercase.

If you want to continue allowing the terminal user to enter the password on the LOGON command, use one of the following methods to support mixed-case passwords:
• If the current USS translate table is used to set all characters to uppercase, the TRANSLATE=NO operand can be added to the USSPARM macros for the corresponding USSCMD, to prevent the specified DATA USSPARM containing the password from being translated to uppercase. For details, see z/OS Communications Server: IP Configuration Reference.
• Do not change the USS command and inform the terminal user to enter the DATA portion of the USS LOGON in single quotes. USS will not translate data within single quotes, and the quotes are removed before the data is passed to the application.
• If the terminal user is specifying only APPLID and DATA on the USS LOGON command, you can use an interpret table. The Telnet Interpret function passes all entered data without translation to the...
application. Specify REMOVE=Y on the LOGCHAR macro to remove the first non blank string from the entered data. Because the terminal user could enter the APPLID in lowercase, you should set up an interpret table that searches for both an uppercase and a lowercase APPLID.

With each of these methods, if the user ID is entered with the password, you must first verify whether the application supports translating the user ID to uppercase. A simple test is to enter the DATA portion of the USS LOGON in single quotes with the user ID specified in lowercase. USS will not translate data within single quotes and the quotes are removed before the data is passed to the application. If the logon fails, the application does not support translating the user ID to uppercase and the terminal user must enter the user ID in uppercase and the password in mixed case for the methods suggested.

**INTERPRET table customization**

The standard Telnet USS logon support should meet the needs of most installations. However, Telnet does support INTERPRET table function if special circumstances require accepting a sequence of characters outside the normal USS command format. For example, the user might want to enter logon data that includes blanks. The INTERPRET table defines all entered data, including blanks, as a USSPARM DATA entry. The PL1 USSCMD format treats each blank as a parameter delimiter and cannot properly process a variable number of parameters. The INTERPRET table character sequences are scanned whenever the client is mapped to both a USS table and an INTERPRET table. Both must be mapped because the INTERPRET function is a subset of the USS function. INTERPRET is not a stand-alone function. The sample INTERPRET table found in SEZAINST(EZBTPINT) is not assembled and linked, and it is not loaded into Telnet as a default INTERPRET table. The table must be assembled, linked, loaded, and mapped in the Telnet profile to be used.

**Creating an INTERPRET table**

Telnet INTERPRET function supports all functions provided by the VTAM INTERPRET definitions. See z/OS Communications Server: IP Configuration Reference for macro details. The following macro instructions are used to create an INTERPRET table:

- INTAB indicates the beginning of the INTERPRET table.
- LOGCHAR defines a single logon message and name of an application program.
- ENDINTAB indicates the end of the INTERPRET table.

Below are some of the more common rules to consider when coding a new INTERPRET table. Also, see the sample found in SEZAINST(EZBTPINT) as a guide.

- The LOGCHAR APPLID= supports APPLICID, ROUTINE and USERVAR.
- Code the most restrictive, or longest, LOGCHAR SEQNCE values first. Otherwise, unexpected matches can occur. The table is scanned from top to bottom until a match is found whether or not it is the most exact match. For example, assume sequence 'LOGA' is assigned APPL1 and any other 'LOG' sequence is assigned APPL2. If sequence 'LOG' is before 'LOGA', entry 'LOGA' will never be found even when the user enters 'LOGA' because entry 'LOG' will be the first match. All sessions will go to APPL2. The problem is corrected by putting 'LOGA' before 'LOG' in the table.

**Assemble, link, and load a table**

Use the sample JCL in SEZAINST(EZBUSJCL). In the sample, the USS table is in USER1.TABLES(USSTEST). It must be assembled and link-edited into the system's linklist or into a library concatenated as a STEPLIB in the TCP/IP startup procedure. In the sample, the table is link-edited into USER1.LINKLIB(USSTEST). The same procedure can be used for the INTERPRET table. Change the name of the input file source and the link-edit target member. The VTAM USS and INTERPRET macros used for the assemble can be found in hlq.SISTMAC1.

**SMF**

The Telnet server writes the following SMF records:

- “Client activity records” on page 621
- “Profile configuration records” on page 621
Network management applications can send these records to a TCP/IP stack for NETMONITOR processing. For more information, see “Real-time SMF information service access control” on page 143.

**Client activity records**

SMF records are written when a user establishes a session (SMF LOGN or Telnet SNA Session Initiation record) and when the session is ended (SMF LOGF or Telnet SNA Session Termination record). Optional SMF recording is controlled by using the SMFINIT and SMFTERM statements.

Two different record formats are available: SMF type 118 and 119. The type 119 records were first introduced in z/OS V1R2 Communications Server, and are controlled by use of the TYPE119/NOTYPE119 operands on the SMFINIT and SMFTERM statements. The subtypes cannot be changed for type 119 records and are set to the STD values. The use of the STD operand or the specification of a nonstandard subtype number on the SMFINIT and SMFTERM parameters control the usage of the older type 118 record processing. Data that are recorded include the application name, Telnet LU name, client and host IP address and port, time of logon or logoff, and data count in and out. Combined with the SMF utility exit routine, SMF data can be used to track Telnet usage by a number of variables. If statements for both format types are coded, then both record types are written. Use that capability sparingly because of the additional processing cost that is involved in generating both types of records. For more information about the layouts for type 118 and type 119 SMF records, see z/OS Communications Server: IP Programmer's Guide and Reference.

**Profile configuration records**

You can control the writing of SMF type 119 Telnet profile configuration records by using the SMFCONFIG statement in the TELNETGLOBALS statement block. The data that is recorded in this SMF record includes the following data:

- Profile data sets used
- Options and values in the TELNETGLOBALS, TELNETPARMS, and BEGINVTAM blocks
- LU mapping statements
- Client identification statements

For more information about the type 119 Telnet profile configuration records, see z/OS Communications Server: IP Programmer's Guide and Reference.

**Connection monitoring mapping statement**

Telnet collects monitoring data for any client connection that is mapped to a MONITORGROUP Object. The collected data can be retrieved several ways:

- Display the data for a single connection using the D TCPIP,tnproc,TELNET,CONN,CONN=connid command.

- A network management agent can request the data from the Telnet SNMP subagent, after the subagent is started by specifying the TNSACONFIG statement. TCPIPJOBNAME must be specified for the subagent to connect with the agent. For information about the TNSACONFIG statement and the parameters needed to start the subagent, see z/OS Communications Server: IP Configuration Reference. For details about configuring the SNMP agent, see Chapter 23, “Simple Network Management Protocol,” on page 1207.

- The Network Management Interface (NMI) Application Programming Interface (API), EZBNMIFR, can be used instead of SNMP to retrieve the data. In this case, the TNSACONFIG statement is not needed. For details about configuring EZBNMIFR and the parameters needed to issue the call, see z/OS Communications Server: IP Programmer's Guide and Reference.

- The Telnet SMF119 session termination record contains two optional sections that can be used to retrieve life-of-session performance data. Life-of-session data is a subset of life-of-connection data. Sliding-window data is not available because data is reported only at the end of the session and not at
periodic intervals. One optional section contains response time statistics (excluding sliding-window) and a second optional section contains response time counts by time bucket. For details on the Telnet server SNA session termination record, see z/OS Communications Server: IP Programmer's Guide and Reference.

Telnet is capable of collecting two types of response time data at the connection level.

- Response time statistics
  - Life-of-connection response time averages
  - Sliding-window response time averages
  - Sum of squares for variance and standard deviation calculations
- Response time counts by time bucket

The MONITORGROUP Object statement in BEGINVTAM is used to set the criteria for monitoring. Options allow the inclusion or exclusion of averages, counts by time bucket, and whether or not the IP network should be included in measurements. When a MONITORGROUP is mapped to Client Identifiers with the MONITORMAP mapping statement, the requested data will be collected for those connections.

Up to 255 MonitorGroups can be active at one time for all ports per Telnet instance. When 255 MonitorGroups are active, no additional groups can be created until some groups are no longer in use by Telnet. A MonitorGroup is considered no longer in use when the group is not defined in a current profile and no connections are using the non-current profile where the MonitorGroup was defined. After being notified that no entries are available, it is up to the operator to manage the removal of some entries by ending connections to free a profile. The operator does not get a notification when an entry becomes available.

Each MonitorGroup entry in the table is assigned an index number. The index number coincides with one of the 255 slots available in the MonitorGroup table. Each Telnet connection entry saves the index number of the MonitorGroup mapped to the connection. When the management application queries a connection for data, it can also query the MonitorGroup table to get the group name and configuration values based on the index found in the connection entry. With the data from the connection and the MonitorGroup criteria from the MonitorGroup table, a management application can generate several summary reports. If a management application is not being used to collect the connection monitoring data, the DTCPIT,tnproc,TELNET,CONN,CONN=connid command can be used to view all the collected data and MonitorGroup information for a single connection.

**Collecting response time data**

The typical Telnet data flow can be represented as shown in Figure 86 on page 622.

![Figure 86. Typical Telnet data flow](image)

Telnet saves timestamp A when it sends a client data request to VTAM, saves timestamp B when the target SNA host application returns data, and saves timestamp C when the client responds to the definite response request that flowed with the reply.
There are many clients, mostly those not supporting TN3270E negotiation, that do not support the
Definite Response (DR) function. In this case, Telnet approximates IP response time by appending a
TIMEMARK request immediately after the data. A Telnet TIMEMARK acts as a synchronization mark or as an "are you there" function for almost all clients. Almost all clients respond to the TIMEMARK request.
Timestamps B and C are set based on when the TIMEMARK request is sent and a TIMEMARK response is received. In rare cases, a client does not respond to a TIMEMARK request. If Telnet does not receive a response to the TIMEMARK, a flag in the connection data indicates that IP transit time measurements were not attempted.

Some installations might not want to incur the additional network traffic of DRs or TIMEMARKs to
measure IP transit time, and are interested only in the SNA application side transit time. In this case, turn
off IP response measurements by specifying NOINCLUDEIP within MonitorGroup. Total response times
will be the SNA response time only.

Specify INCLUDEIP within the MonitorGroup to include IP response measurements when monitoring a
connection. It does not matter whether the SNA host application requested a definite response on its
reply. Many applications save processing time and IP transactions by not requesting Definite Response. If
IP response time monitoring is wanted and the client supports DR, specify DYNAMICDR within
MonitorGroup to add the definite response request to ensure that a response is received from the client.
In this case, Telnet does not forward the response to the target SNA host application, as indicated by the
dotted line in Figure 86 on page 622. Specify NODYNAMICDR to turn off dynamic DR creation. If
INCLUDEIP and NODYNAMICDR are specified and data from the application does not include a DR
request, the TIMEMARK method is used.

If chained data is sent from the host application, Telnet collects the entire chain before sending the
complete data stream to the client. Telnet will save timestamp B when the entire data chain is sent.

It should be pointed out that the measured response time might not be exactly what the user sees. The
first timestamp, A, is recorded when the data passes from Telnet to VTAM on its way to the SNA VTAM
application. For various SNA reasons, Telnet might have received the data much earlier and had to queue
it before it could be sent to VTAM. The most common reason for this is the application might not have
given Telnet direction (the ability to send data). SNA applications often use a Change Direction Indicator
(CDI) to manage which side can send data. The current sender can send data until it sends a CDI, which
gives the other side permission to send. There might be scenarios where a client data request comes in,
Telnet does not have direction, and must queue the data until the application sends a CDI. The measured
response time will not include this queue time.

**Average response time data collection**

Specify AVERAGE within MonitorGroup to collect average response time data. Specify NOAVERAGE to turn
off average response time data collection. If average response time data is requested, the following data
is available on a per connection basis:

- Life-of-connection response time averages
- Sliding-window response time averages
- Variance and standard deviation of response time averages

**Life-of-connection response time averages**

These averages are based on data collected since the beginning of the connection. Data collected for this
average includes:

- Total transaction count.
- Sum of the round-trip response times. Round-trip response time is the time difference between
timestamp C and timestamp A.
- Sum of the IP response times. IP response time is the time difference between timestamp C and
timestamp B. Sum of the SNA response times can be derived by subtracting the IP sum from the round-
trip sum.

With this data collected, the average round-trip time, average IP time, and average SNA time can be
calculated by dividing each sum by the transaction count. The data accumulation values might wrap. It is
up to the management application to detect this. The Telnet connection display will indicate the wrapped condition instead of displaying averages.

**Sliding-window response time averages**

These averages give higher significance to more recent data without ever completely losing the impact of earlier data. The sliding-window methodology calculates an average over an interval of time instead of over the life of the connection. An interval is made up of a specified number of equal time periods. Use AVGSAMPMULTIPLIER to specify how many periods are in the interval. Use AVGSAMPPERIOD to specify the time length of a period. An interval should be long enough to have several data flows measured. Data collected during the period includes:

- Transaction count in the period (pTX).
- Sum of round-trip response times in the period (pRT).
- Sum of IP response times in the period (pIP). Sum of SNA response times can be derived.

In addition, there are three sliding-window variables that represent the interval and are used to calculate the sliding-window average. These variables are updated at the end of each period. They are:

- Sliding-window transaction count (swTX).
- Sliding-window sum of round-trip response times (swRT).
- Sliding-window sum of IP response times (swIP). Sliding-window sum of SNA response times can be derived.

When the interval has moved one period, subtracting the oldest period of collected data from the total and adding the newest period is one method for determining the new interval averages. However, this simple method loses all impact of earlier periods on the averages. Instead of dropping the collected data from the oldest period in the interval and completely losing its effect on the average, an average period of data is subtracted from the sliding-window totals. With this method, even the oldest period data continues to have a declining effect on the latest average calculations. And, by using an average period amount, the unique data for each period does not need to be retained. Only a total for the entire interval needs to be saved. Average period data is determined based on the fact that a period is a fraction of the total interval time. A period of data is $1/n$ of the current sliding-window totals, where $n$ is the number of periods in the interval. The sliding-window average is derived from the new sliding-window values. At the end of each period the following calculations occur:

- Calculate the average period values:

  \[
  \begin{align*}
  \text{avTX} &= \text{swTX} \times \frac{1}{n} \\
  \text{avRT} &= \text{swRT} \times \frac{1}{n} \\
  \text{avIP} &= \text{swIP} \times \frac{1}{n}
  \end{align*}
  \]

- Remove an average period amount from the sliding-window totals and add the new period values:

  \[
  \begin{align*}
  \text{swTX} &= \text{swTX} - \text{avTX} + \text{pTX} \\
  \text{swRT} &= \text{swRT} - \text{avRT} + \text{pRT} \\
  \text{swIP} &= \text{swIP} - \text{avIP} + \text{pRT}
  \end{align*}
  \]

- Calculate and report new sliding-window averages:

  \[
  \begin{align*}
  \text{sliding-window round-trip average} &= \frac{\text{swRT}}{\text{swTX}} \\
  \text{sliding-window IP average} &= \frac{\text{swIP}}{\text{swTX}} \\
  \text{sliding-window SNA average} &= \frac{\text{swRT} - \text{swIP}}{\text{swTX}}
  \end{align*}
  \]

After the calculations are done, the period variables are reset and the next period of data collection begins. At the end of that period, the sliding-window variables are updated again with new information. The cycle continues for the life of the connection.

AVGSAMPMULTIPLIER 1 is a special case where 100% of the existing interval data is subtracted before the new period data is added. The result is an average for just that interval and the effect of older data is completely ignored.

AVGSAMPMULTIPLIER 0 is a special case that tells Telnet to include all data equally. The result is a life-of-connection average that is already available. A very large multiplier will have a similar effect.
A sliding-window round-trip average example follows. Assume an interval is made up of 5 periods. Each period is 2 minutes. Specify AVGSAMPMULTIPLIER 5 and AVGSAMPPERIOD 120. For illustrative purposes in this example, the average response time starts low and then increases to a steady state value. The data collected for each period is the sum of all response times in milliseconds (ms) and the number of transactions (tx).

<table>
<thead>
<tr>
<th>Period</th>
<th>Sum of response times (ms)</th>
<th>Number of transactions (tx)</th>
<th>Average response time (ms/tx)</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1000</td>
<td>10</td>
<td>100</td>
</tr>
<tr>
<td>2</td>
<td>1650</td>
<td>15</td>
<td>110</td>
</tr>
<tr>
<td>3</td>
<td>2800</td>
<td>20</td>
<td>140</td>
</tr>
<tr>
<td>4</td>
<td>3500</td>
<td>25</td>
<td>140</td>

<tr>
<td>6</td>
<td>4900</td>
<td>35</td>
<td>140</td>
</tr>
<tr>
<td>7</td>
<td>5600</td>
<td>40</td>
<td>140</td>
</tr>
</tbody>
</table>

The sliding-window average response time for period 1:

\[ \frac{1000\text{ms}}{10\text{tx}} = 100 \text{ ms/tx} \]

The sliding-window average response time for period 2:

\[ \frac{(1000-(1000*(1/5))+1650)\text{ms}}{(10-(10*(1/5))+15)\text{tx}} = \frac{2450\text{ms}}{23\text{tx}} = 106.5 \text{ ms/tx} \]

The sliding-window average response time for period 3:

\[ \frac{(2450-(2450*(1/5))+2800)\text{ms}}{(23-(23*(1/5))+20)\text{tx}} = \frac{4760\text{ms}}{38.4\text{tx}} = 124.0 \text{ ms/tx} \]

The sliding-window average response time for period 4:

\[ 7308\text{ms}/55.7\text{tx} = 131.2 \text{ ms/tx} \]

The sliding-window average response time for period 5:

\[ 10046.4\text{ms}/74.6\text{tx} = 134.7 \text{ ms/tx} \]

The sliding-window average response time for period 6:

\[ 12937.1\text{ms}/94.7\text{tx} = 136.6 \text{ ms/tx} \]

The sliding-window average response time for period 7:

\[ 15949.7\text{ms}/115.7\text{tx} = 137.9 \text{ ms/tx} \]

The sliding-window method continues to include the effects of the earlier response time averages. The greater the number of periods (AVGSAMPMULTIPLIER), the longer older data will continue to impact new average calculations. Decreasing the number of periods (AVGSAMPMULTIPLIER) gives less emphasis to older data. The AVGSAMPMULTIPLIER gives the system administrator control over the emphasis placed on old data.

Each of the last five periods in the example had average response times of 140 ms/tx. Different multiplier values give the following results after seven periods. It is clear that the greater the number of periods in the interval, the greater the impact of the older data.

- 2 period interval - 139.7 ms/tx
Variance and standard deviation of response time averages

It is useful to know the dispersion of the response time data. The variance is a measure of how variable the data is. The square root of the variance is the standard deviation. Assuming the distribution is a normal distribution, you can have the following confidence level:

- 68% that a response time value will fall within the average, plus or minus 1 standard deviation
- 95% that a response time value will fall within the average, plus or minus 2 standard deviations
- 99% that a response time value will fall within the average, plus or minus 3 standard deviations

The data that is saved for variance and standard deviation includes the data that is saved for life-of-connection averages, and the sum of each response time squared for the following data:

- Complete round-trip.
- IP portion of the transaction.
- SNA portion of the transaction. The sum of squares cannot be derived in this case and must be separately maintained.

These values might wrap. It is up to the management application to detect this. The Telnet connection display will indicate the wrapped condition instead of displaying these values or the standard deviation. The typical formula used for variance is:

\[
\text{VARIANCE} = \frac{\sum((X_i - \text{Xm})^2)}{(n-1)}
\]

However, that would require keeping all the individual response times to calculate the sum of the squares. The same formula can be expanded and rewritten to not need individual response times. The formula used by Telnet is:

\[
\text{VARIANCE} = \frac{\left[\sum(X_i^2) - \left(\sum(X_i)\right)^2/n\right]}{(n-1)}
\]

The values needed in this formula are saved by Telnet for each connection requesting average response time monitoring.

Time buckets

Five time buckets, each defined by a maximum response time, are used. Every transaction has a total response time, and that time fits into one of the five configurable time buckets. The bucket boundaries are created by specifying the maximum response time for the first four buckets. The fifth bucket has an open-ended maximum value. The minimum response time boundary for each bucket is the maximum of the previous bucket. The first bucket has a minimum value of 0. A bucket transaction count is incremented by one when a response time is greater than the minimum and less than or equal to the maximum. Figure 87 on page 626 depicts the time buckets. For default values, see z/OS Communications Server: IP Configuration Reference.

![Figure 87. Time buckets](image)

Reducing demand for ECSA storage

Telnet server configurations that support a large number of connections can place a high demand on ECSA storage. To reduce this demand, configure the Telnet server to enable multiple Telnet LUs to share an ACB.
To configure the Telnet server to enable LUs to share an ACB, specify SHAREACB in the TELNETGLOBALS statement block. Replace any predefined (static) VTAM APPL definitions that are being used to represent Telnet LUs with corresponding model application program definitions; the latter are required when using the SHAREACB function.

Configuring the z/OS UNIX Telnet server

The z/OS UNIX Telnet server (otelnetd) provides access to z/OS UNIX shell applications on the host using the Telnet protocol. The z/OS UNIX Telnet server lets hosts in an IP network log on to the z/OS shell environment directly, without going through TSO. The z/OS UNIX Telnet server supports AIX and UNIX full-screen applications such as the vi editor, so that AIX and UNIX users can use familiar Telnet commands. The z/OS UNIX Telnet server runs in both line mode and raw mode, but does not support TN3270 or TN3270E, as the TN3270E Telnet server does.

Installation information

The files used in the z/OS UNIX Telnet server and their locations in the z/OS UNIX file system are as follows:

/etc/services

The ports for each application are defined here. For example:

```plaintext
otelnet xxxx/tcp
```

where xxxx is the port that inetd should listen on for otelnet.

/etc/syslog.conf

The configuration parameters for usage of syslogd are defined in this file. otelnetd writes to syslog facility local1.

/etc/inetd.conf

The configuration parameters for all applications started by inetd are defined in this file.

/usr/sbin/otelnetd

This is a symbolic link to /usr/lpp/tcpip/sbin/otelnetd. /usr/lpp/tcpip/sbin/otelnetd is a sticky-bit file. The OTELNETD member of SEZALOAD contains the executable code for the Telnet server.

/etc/banner

This file contains a login message that is printed to the client's screen after the client logs in, unless the -h option is specified. Store the banner in this file.

/etc/otelnetd.banner

This file contains a message that is printed to the client's screen prior to the login prompt when the user connects to the server, unless the -h option is specified. Store the banner in this file.

/etc/utmpx

This file is updated by the call to fsumoclp. It contains a list of all the users who are logged in with their associated tty.

/dev/ptypXXXX and /dev/ttypXXXX

These special device files represent pseudoterminals (ptys); they are used by the z/OS UNIX Telnet server and other programs.

**Note:** For information on allocating more of these files for more connections, see z/OS UNIX System Services Planning.

/usr/share/lib/terminfo

The descriptions of supported terminals are stored here. For more information, see z/OS UNIX System Services Planning.

/usr/lib/nls/msg/C/tnmsgs.cat

The message catalog used by the z/OS UNIX Telnet server is stored here.
If the message catalog does not exist, the software will use the messages hard-coded within the software by default. These messages duplicate the English message catalog that is shipped with the product.

/usr/man/C/cat1/otelned.1

This file contains the associated manual (man) pages for the z/OS UNIX Telnet server. It provides online help for the user.

Environment variables

Table 30 on page 628 provides a list of environment variables that can be explicitly set by z/OS UNIX Telnet.

<table>
<thead>
<tr>
<th>Environment variable</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>_BPX_SHAREAS</td>
<td>Controls whether a spawned child process is started in the same address space as the login shell.</td>
</tr>
<tr>
<td>KRB5_SERVER_KEYTAB</td>
<td>Specifies the location of the key table.</td>
</tr>
<tr>
<td>LC_ALL</td>
<td>Determines the values for all local categories.</td>
</tr>
<tr>
<td>LC_COLLATE</td>
<td>Determines the local category for character collation.</td>
</tr>
<tr>
<td>LC_CTYPE</td>
<td>Determines the local category for character handling functions, such as tolower(), toupper(), and isalpha(). Also determines the interpretation of sequences of bytes of text data as characters (for example, single as opposed to multibyte characters), the classification of characters (for example, alpha, digit, graph), and the behavior of character classes.</td>
</tr>
<tr>
<td>LC_MESSAGES</td>
<td>Determines the local category for processing affirmative and negative responses, and the language and cultural conventions in which messages should be written.</td>
</tr>
<tr>
<td>LC_NUMERIC</td>
<td>Determines the local category for numeric formatting information (for example, thousands separator and radix character) in various utilities, as well as the formatted I/O operations in printf() and scanf() and the string conversion functions in strtod().</td>
</tr>
<tr>
<td>LC_TIME</td>
<td>Determines the local category for date and time formatting information. It affects the behavior of the time functions in strftime(). Additional semantics of this variable, if any, are implementation defined.</td>
</tr>
<tr>
<td>NLSPATH</td>
<td>Contains a sequence of templates that the catopen() function uses when attempting to locate message catalogs. Each template consists of an optional prefix, one or more conversion specifications, a file name, and an optional suffix.</td>
</tr>
<tr>
<td>TERMINFO</td>
<td>Specifies the path name for an unsupported terminal that has been added to the terminfo file. Use the TERMINFO variable in /etc/profile or /etc/.login.</td>
</tr>
</tbody>
</table>

Starting, stopping, and administration of z/OS UNIX Telnet

The z/OS UNIX Telnet server is started by inetd for each incoming Telnet connection. When the Telnet session is complete, the z/OS UNIX Telnet server will exit. Each active Telnet session will have a separate instance of the Telnet server which will communicate with the Telnet client.

The z/OS UNIX inetd daemon does not propagate environment variables other than PATH and TZ to its child processes, so the NLSPATH and LANG environment variables cannot be used to point to a different message catalog.
The following standards are supported:

- RFC 854 Telnet Protocol Specification
- RFC 855 Telnet Option Specification
- RFC 856 Telnet Binary Transmission
- RFC 857 Telnet Echo Option
- RFC 858 Telnet Suppress Go Ahead Option
- RFC 859 Telnet Status Option
- RFC 860 Telnet Timing Mark Option
- RFC 861 Telnet Extended Options - List Option
- RFC 885 Telnet End of Record Option
- RFC 1073 Telnet Window Size Option
- RFC 1079 Telnet Terminal Speed Option
- RFC 1091 Telnet Terminal type option
- RFC 1096 Telnet X Display Location Option
- RFC 1123 Requirements for Internet Hosts -- Application and Support
- RFC 1184 Telnet Linemode Option
- RFC 1372 Telnet Remote Flow Control Option
- RFC 1571 Telnet Environment Option Interoperability Issues
- RFC 1572 Telnet Environment Option
- RFC 2941 Telnet Authentication Option
- RFC 2942 Telnet Authentication: Kerberos Version 5
- RFC 2946 Telnet Data Encryption Option
- RFC 2952 Telnet Encryption: DES 64 bit Cipher Feedback
- RFC 2953 Telnet Encryption: DES 64 bit Output Feedback

When a z/OS UNIX Telnet session is started up, otelnetd sends Telnet options to the client side that indicate a willingness to do the following options:

- WILL ENCRYPT
- DO ENCRYPT
- DO TERMINAL TYPE
- DO TSPEED
- DO XDISPLOC
- DO NEW-ENVIRON
- DO ENVIRON
- WILL SUPPRESS GO AHEAD
- DO ECHO
- DO LINEMODE
- DO NAWS
- WILL STATUS
- DO LFLOW
- DO TIMING-MARK

The z/OS UNIX Telnet server can enable the following options locally.

- WILL BINARY
This option indicates that the client is willing to send 8 bits of data, rather than the normal 7 bits of network virtual terminal data.

- **WILL ECHO**

  When the LINEMODE option is enabled, a WILL ECHO or WONT ECHO is sent to the client to indicate the current state of terminal echoing. When terminal echo is not wanted, a WILL ECHO is sent to indicate that Telnet takes care of echoing any data that must be echoed to the terminal, and then nothing is echoed. When terminal echo is wanted, a WONT ECHO is sent to indicate that Telnet is not doing any terminal echoing, so the client can do any terminal echoing that is needed.

- **WILL LOGOUT**

  When a DO LOGOUT is received, a WILL LOGOUT is sent in response and the Telnet session is shut down.

- **WILL SGA**

  This option indicates that it will not be sending IAC GA, the go ahead command.

- **WILL STATUS**

  Indicates a willingness to send the client, upon request, the current status of all Telnet options.

- **WILL TIMING-MARK**

  Whenever a DO TIMING-MARK is received, a WILL TIMING-MARK is the response. It is used only in kludge linemode support.

- **WILL ENCRYPT**

  Indicates a willingness to encrypt the data stream.

The z/OS UNIX Telnet server can enable the following options remotely.

- **DO BINARY**

  Sent to indicate that Telnet is willing to receive an 8-bit data stream.

- **DO ECHO**

  If a WILL ECHO is received, a DONT ECHO will be sent in response.

- **DO ENVIRON**

  Indicates a desire to be able to request environment variable information. (See RFC 1408.)

- **DO LFLOW**

  Requests that the client handle flow control characters remotely.

- **DO LINEMODE**

  Supports requests that the client do line-by-line processing.

- **DO NAWS**

  Requests that the client inform the server when the window size changes.

- **DO NEW-ENVIRON**

  Indicates a desire to be able to request environment variable information. (See RFC 1572.)

- **DO SGA**

  Indicates that it does not need to receive IAC GA, the go ahead command.

- **DO TERMINAL-TYPE**

  Indicates a desire to be able to request the name of the type of terminal that is attached to the client side of the connection.

- **DO TERMINAL-SPEED**

  Indicates a desire to be able to request information about the speed of the serial line to which the client is attached.
• **DO TIMING-MARK**
  Only supported if the client responded with WONT LINEMODE. If the client responds with WILL TM, then it is assumed that the client will support kludge linemode. It is not used for any other purposes.

• **DO XDISPLOC**
  Indicates a desire to be able to request the name of the X Window System display that is associated with the Telnet client.

• **DO AUTHENTICATION**
  Indicates a willingness to receive authentication information for automatic login.

• **DO ENCRYPT**
  Indicates a willingness to decrypt the data stream.

**otelnetsd**

**Note:** The user ID associated with the daemon in `/etc/inetd.conf` requires superuser authority. See z/OS UNIX System Services Planning for a description of the types of authority defined for daemons.

The following syntax is used in the `/etc/inetd.conf` file to define the arguments used to invoke otelnetsd.

**Syntax**

```
otelnetd
  -C
  -D
  -h
  -k
  -l
  -m
  -n
  -t
  -U
  -g
  -b
  -c timeout_value
  -T terminfo_value
  -X authtype
  -s
```
Parameters

-C
Prints user messages in uppercase. There are several exceptions. Messages issued at startup are not affected by the -C option because the -C option is not processed during the startup. Also, data transmittal messages will not be uppercase. Data transmittal messages are generated from the -D netdata option or the -D ptydata option.

-D
The following suboptions apply to -D:

  options
  Prints information about the negotiation of Telnet options. This information is used for debugging purposes. This suboption allows telnetd to generate debugging information to the connection, which allows the user to view telnetd activity.

  report
  Prints the options information and additional information about processing. This information also includes print information designated for suboption=options. This can be used for debugging purposes. This suboption telnetd to generate debugging information to the connection, which enables the user to view telnetd activity.

  netdata
  Displays the data stream received by telnetd. This information is used for debugging purposes. It allows telnetd to generate debugging information to the connection, which enables the user to view telnetd activity.

  ptydata
  Displays the data stream written to the pty. This information is used for debugging purposes. It allows telnetd to generate debugging information to the connection, which enables the user to view telnetd activity.

  all
  Enables options, report, netdata, ptydata, login, authentication and encryption.

  login
  Records login and logout activity to syslogd facility auth using message EZYTU36I.

  authentication
  Turns on authentication debugging code.

  encryption
  Turns on encryption debugging code.

-h
Disables the display of the /etc/banner and /etc/otelnetd.banner files at the terminal of the client.

-k
Disables kludge linemode. The server normally attempts to use kludge linemode when the -l option was specified, but the client does not support line mode. Use the -k option when there are remote clients that do not support kludge linemode, but pass the heuristic for kludge line mode support (for example, if they respond with WILL TIMING-MARK in response to a DO TIMING-MARK). This option does not disable kludge line mode when the client requests it. This is accomplished by the client sending DONT SUPPRESS-GO-AHEAD and DONT ECHO.

-l
Specifies linemode, which tries to force clients to use linemode. If the LINEMODE option is not supported and the -k option was not specified, it will attempt to use kludge linemode.

Notes:
1. Many clients decline the server's request to operate in linemode.
2. Linemode is not appropriate for full-screen applications like the z/OS UNIX vi editor.

-m
Enables the creation of a forked or spawned process to coexist in the same address space. This option can improve performance because the user's login shell runs in the same address space as telnetd.
-n
Disables TCP keep-alives. Normally, telnetd enables the TCP keep-alive mechanism to probe connections that have been idle for some time to determine if the client is still there. In this way, idle connections from machines that have crashed or can no longer be reached can be cleaned up. The cleanup of disabled connections is controlled by the presence of the INTERVAL parameter on the TCPCONFIG statement in the TCPIP profile.

-t
Specifies internal tracing. It also activates the REPORT option, as if the user also specified -D Report.

-U
Causes telnetd to drop connections from any IP address that cannot be mapped back into a symbolic name by the gethostbyaddr or getnameinfo routines.

Result: If coded, the -U parameter causes the -g parameter to be ignored.

-g
Disables the ability to issue the gethostbyaddr or getnameinfo routines that use the client IP address to resolve the client host name.

Results:
- If this parameter is coded, the host name does not appear in the trace output (-t parameter) or in the WHO command output.
- This parameter is ignored if the -U parameter is coded.

-b
Forces the server to DO BINARY in the first pass during negotiations with the client.

-c timeout_value
Specifies the number of seconds to wait before terminating the Telnet session for inactive connections. The timeout_value is a value between 1 and 86400 seconds.

-T terminfo_value
Sets the TERMINFO environment variable to the specified values at startup. This option is needed when terminfo definitions are located in nonstandard directories.

-a
This option may be used for specifying what mode should be used for authentication. There are several valid suboptions for authentication mode:

valid
Allow connections only when the remote user can provide valid authentication information to identify the remote user. Thus, for otelnetd, Kerberos authentication will be required. User verification will still occur through the login and password prompt. However, if the login user ID matches the TSO user ID that was mapped from the name in the Kerberos principal using the SAF R_usermap function, then no password will be requested. This is the most secure authentication mode.

other
Allow only connections that supply some authentication information. This option is currently not supported by any of the existing authentication mechanisms, and is thus the same as specifying -a valid.

user
Allow connections only when the remote user can provide valid authentication information to identify the remote user, and is allowed access to the specified account without providing a password. Thus, for otelnetd, Kerberos authentication is required. The NAME received during AUTHENTICATION option negotiation must match the name in the Kerberos principal, and the Kerberos principal must map to a valid TSO user ID on the host using the SAF R_usermap function. No user verification will occur through the login or password prompt.

none
This is the default state. Authentication information is not required. User verification will still occur through the login and password prompt. However, if the login user ID matches the TSO user ID
that was mapped from the name in the Kerberos principal using the SAF R_usermap function, then no password will be requested.

**off**
This disables the authentication code. All user verification happens through the login and password prompt. During option negotiation, otelnetd will not send DO AUTHENTICATION and, if necessary, will send DONT AUTHENTICATION.

**Note:** Authentication is not supported for IPv6 connections. If tcp6 is specified in inetd.conf, -a should not be used as a start option. If tcp6 and -a are both specified, the suboption will be overridden and forced to OFF.

**-X authtype**
This option disables the use of authtype authentication. Currently the only valid value for authtype is KERBEROS_V5. Thus, if otelnetd sends the AUTHENTICATION option SEND command, the authentication-type-pair-list will not contain any KERBEROS_V5 entries and will be empty.

**-s**
Used to set the KRB5_SERVER_KEYTAB environment variable. If this environment variable is set, run time security uses a local instance of the Kerberos security server to decrypt service tickets instead of obtaining the key from a key table. To use this capability, the otelnetd application must have at least READ access to the IRR.RUSERMAP resource in the FACILITY class. For more information, see z/OS Integrated Security Services Network Authentication Service Administration.

**SMF record handling**
The SMF records generated are the typical set of records that MVS generates for start of job (login) and end of job (logoff). Additionally, interval records might be issued during the life of the user login. These records are SMF type 30 and type 72 and not the type 118 or type 119 in the current z/OS UNIX Telnet server. The process of issuing these records is external to the specific daemons.

**BPX.DAEMON considerations**
If the BPX.DAEMON FACILITY class profile is defined, perform the following additional configuration steps:

1. Provide read access to BPX.DAEMON for the user ID specified in /etc/inetd.conf for otelnetd.
2. Define SEZALOAD to program control.
3. Define the C run-time library, hlq.SCEERUN to program control.

See z/OS UNIX System Services Planning for more information about the BPX.DAEMON FACILITY class profile, the security product commands used to perform the required configuration, and the diagnosis procedure for resolving related problems.

**Kerberos**
otelnetd supports Kerberos Version 5 for authentication on IPv4 connections. Authentication is not supported on IPv6 connections (that is, if tcp6 is specified for otelnetd in inetd.conf). On z/OS, Kerberos is implemented by Security Server. See z/OS Integrated Security Services Network Authentication Service Administration for more information.

If you plan to use Kerberos authentication with otelnetd, you need to ensure that the user ID under which inetd runs has permission to the ICSF callable services that Kerberos needs. Specifically, if the CSFSERV class is active, ensure that the user ID of inetd has read access to the following ICSF SAF resources:

- CSF1TRC
- CSF1SKE
- CSF1SKD
- CSF1TRD
- CSFOWH

The Kerberos principal used by otelnetd will generally be of the form "host/<hostname>@realm". That is, the first component of the Kerberos principal is "host"; the second component is the fully qualified lowercase hostname of the server; and the realm is the Kerberos realm to which the server belongs. otelnetd will not accept forwarded credentials from the client.
Successful AUTHENTICATION option negotiation is required for successful ENCRYPT option negotiation. The ENCRYPT option must be negotiated in both directions.
Chapter 12. Transferring files using FTP

The File Transfer Protocol (FTP) allows a user to copy files from one machine to another. The protocol allows for data transfer between the client (the user) and the server in either direction. In addition to copying files, the client can issue FTP commands to the server to manipulate the underlying file system of the server (for example, to create or delete directories, delete files, rename existing files, and so on.) FTP is the most common TCP/IP application for moving files between computers.

Copying files from one machine to another is one of the most frequently used operations. The data transfer between client and server can be in either direction. The client can send a file to the server machine. It can also request a file from this server.

To access remote files, the user must identify himself or herself to the server. At this point the server is responsible for authenticating the client before it allows the file transfer.

From an FTP user's point of view, the link is connection-oriented. FTP uses TCP as a transport protocol to provide reliable end-to-end connections. Both hosts must run TCP/IP to establish file transfer.

The z/OS model for the FTP server includes a daemon process and a server process. The daemon process starts when you start your cataloged procedure (for example, START FTPD) and it listens for connection requests on a specific port. The port is the well-known port 21 unless otherwise specified. For methods of choosing a different port number, see “Configuring ETC.SERVICES” on page 639 and “Configuring the FTPD cataloged procedure” on page 639. When the daemon accepts an incoming connection, it creates a new process (server's address space) for the FTP server, which handles the connection for the rest of the FTP login session. Each login session has its own server process.

The server process inherits the accepted connection from the daemon process. This connection is called the control connection. The server receives commands from the client and sends replies to the client using the control connection. The control connection port is the same as the daemon's listening port.

The client and server use a different connection for transferring data; this connection is called the data connection. By default, the data port is one less than the control connection port. For example, if the control connection port is 21, the data port is 20. An FTP client can override the default data port by directing the server to run in passive mode. In passive mode, the server uses an ephemeral port for the data port. Passive mode is requested by firewall friendly clients and by clients initiating three-way data transfers.

Notes:

1. This topic discusses RACF configuration required for FTP. References to RACF apply to any other SAF-compliant security products that contain the required support. If you are using another security product, read the documentation for that product for instructions on configuration.

2. If you use the environment variable _BPX_JOBNAME when you start FTPD, the server's address space is known as the job name specified in the _BPX_JOBNAME variable. You might need to have a common naming convention for your installation's FTP address spaces if your installation uses syslogd isolation or has other workload management requirements.

If you do not use the _BPX_JOBNAME environment variable, the server's address space assumes the name of the user. For example, if a user logs into an FTP server with the user ID TCP0001, the FTP server address space servicing the request is also known as TCP0001.

If the FTP daemon accepts a connection that is protected by the TLS security mechanism and you are not using the _BPX_JOBNAME environment variable, the server's address space name is a name derived from the FTP server job name. The name is in the form jobnamex, where the jobname value is the job name, and the x value is a number in the range 1 – 9. If the FTP daemon accepts a connection that is protected by the TLS security mechanism and you are using the _BPX_JOBNAME environment variable, the server's address space name is a name derived from the _BPX_JOBNAME environment variable. The name is in the form bpxjobnamex, where the bpxjobname value is the value specified for the _BPX_JOBNAME environment variable, and the x value is a number in the range 1-9.

Configuring PROFILE.TCPIP for FTP

If you have configured the FTP server to have affinity to a specific stack, or you have configured the FTP server to be a generic server in a single stack environment, the FTP server can be started automatically when the TCP/IP address space is started by specifying the name of the FTP server cataloged procedure in the AUTOLOG statement. If you have configured the FTP server as a generic server in a multiple stack environment, you should not use the AUTOLOG statement to automatically start the server. Instead, use some other automation outside of AUTOLOG to automatically start the server.

In the following example, if your procedure is called FTPD, the following statement allows TCP/IP to issue the MVS START command for procedure FTPD. The job name of FTPD1 will be used on the port statement shown below. If the daemon job name is fewer than eight characters, the FTP daemon forks a process that has the job name of the original daemon appended with the numeral 1.

```
AUTOLOG
  FTPD  JOBNAME FTPD1
ENDAUTOLOG
```

To reserve ports 21 and 20 for the FTP server, add the following statement:

```
PORT
  21 TCP FTPD1 ; FTP server control port
  20 TCP OMVS NOAUTOLOG ; FTP server data port
```

Specifying FTPD1 on the PORT and AUTOLOG statements directs TCP/IP to restart FTPD if it should end.

To allow FTP to detect data connection errors when there has been no activity on the data connection for a certain amount of time, set the INTERVAL parameter on the TCPCONFIG statement to a relatively low value. The keepalive packets that the stack sends as specified on the INTERVAL parameter enable the stack to detect errors, such as a reset or terminated peer connection, instead of waiting indefinitely. Be careful when choosing an INTERVAL value on the TCPCONFIG statement because this value will affect all TCP connections at the host for which the interval has been activated, not just FTP connections.

The control connection can also benefit from keepalive packets. Many firewalls require periodic activity on any connection that is made and the control connection can appear idle during a long data transfer. Coding the INTERVAL parameter on the TCPCONFIG statement will, of course, cause keepalive packets to be sent on the control connection as well as the data connection. You can override the keepalive interval that you have configured in the stack for the FTP control connection and data connection with the FTPKEEPALIVE (control connection) and DATAKEEPALIVE (data connection) statements in the FTP.DATA file or data set.

Optimally, FTP needs a buffer size of at least 180K for data connections. You should not set the TCPMAXRCVBUFSIZE parameter below 180K. The default value for the parameter is 256K. IBM Health Checker for z/OS can be used to check whether the TCPMAXRCVBUFSIZE value is sufficient to provide optimal support to the z/OS Communications Server FTP server. For more details about IBM Health Checker for z/OS, see z/OS Communications Server: IP Diagnosis Guide and IBM Health Checker for z/OS: User’s Guide.

For more information about the AUTOLOG, PORT, and TCPCONFIG statements, see z/OS Communications Server: IP Configuration Reference.

If your FTP server accepts connections on a distributed Dynamic VIPA (DVIPA), SYSPLEXPORTS must be specified for the distributed DVIPA if either of the following conditions are true:

- The DVIPA is an IPv6 address.
- Passive mode FTP is used.

For more information about the VIPADYNAMIC statement and specifying the SYSPLEXPORTS option on the VIPADISTRIBUTE parameter, see z/OS Communications Server: IP Configuration Reference.
Configuring ETC.SERVICES

The ETC.SERVICES file contains the relationship between service names (servers) and port numbers in the z/OS UNIX environment. If necessary, update your ETC.SERVICES file to include the control port that the FTP server is to use. For the search order used to locate the ETC.SERVICES file, see “Configuration files for TCP/IP applications” on page 25. For example, add the following line:

```
ftp 21/tcp
```

Notes:

1. In the ETC.SERVICES file, only one port (the one for the control connection) is listed.
2. If the ETC.SERVICES file is changed such that a port other than 21 is specified, that port will become the FTP port for that z/OS host.
3. The port specified for FTP in the ETC.SERVICES file can be overridden by the FTP start parameter, PORT nnnn. In either case, the port that is specified should match the port specified for FTP on the PORT statement in PROFILE.TCPIP.

Configuring /etc/syslog.conf

Note: For FTP syslog, you should consider the fact that FTP writes log messages to the system console if syslogd is not running. If you enable FTP server traces without syslogd active, large amounts of data might be written to the system console.

The daemon.priority entries in /etc/syslog.conf determine where FTP messages and trace entries are written. The FTP server issues info, warning, and error messages. All trace entries are written with debug priority. To direct trace entries (and all messages) to /tmp/daemon.trace, include the following line in /etc/syslog.conf:

```
*.daemon.debug /tmp/daemon.trace
```

Log messages can be isolated within syslogd. For FTP, an installation might want FTP log messages to be written to different files depending on the user ID, or separately for the FTP daemon. If FTP messages are to be isolated for user1, use the first statement below. If FTP messages are to be logged for all the FTP applications, use the second statement below.

```
user1.*.daemon.debug /tmp/daemon.trace

.*.FTPD*.daemon.debug /tmp/daemon.trace
```

In this statement, it is assumed that_BPX_JOBNAME is set to FTPD.

Configuring the FTPD cataloged procedure

The FTPD catalogued procedure is sample JCL that you can use to start the FTP server. To use the sample, you must modify it to suit your needs.

Before you begin

You must configure TCP/IP and your security product. You will modify the configuration of your security product for use with your FTP server.

Procedure

Perform the following steps to configure the FTPD catalogued procedure:

1. Copy the sample in SEZAINST(FTPD) to your system or recognized PROCLIB.
2. Update the SYSFTPD DD and SYSTCPD statements.
   See “Configuring FTP.DATA” on page 649 to configure SYSFTPD DD and “Configuring TCPIP.DATA for FTP” on page 649 to configure SYSTCPD DD.

3. Decide whether you will pass start parameters in the FTPD catalogued procedure.
   • If you are not going to pass start parameters, add your parameters to the FTP.DATA file.
   • If you are going to pass start parameters, add your parameters to the PARMS parameter in the PROC statement of the FTPD catalogued procedure.

   Any parameters that you modify in the PROC statement override parameters that are set in the FTPDATA file.

   The system parameters required by the FTP server are passed by the PARM parameter on the EXEC statement of the FTPD catalogued procedure. For example, the entry //FTPD PROC MODULE='FTP',PARMS='TRACE ANONYMOUS PORT 21' starts FTP with tracing active, anonymous support enabled, and using control port 21.

   For more information about the FTP server cataloged procedure (FTPD) parameters, see z/OS Communications Server: IP Configuration Reference.

4. Define the FTPD catalogued procedure to the security program.
   Add the FTPD catalogued procedure to the RACF STARTED class facility or to the started procedures table.

   The user ID that is associated with the FTP server STARTED class must have UID 0. If the FACILITY class is active and the BPX.DAEMON or BPX.POE profiles are defined, the user ID that is associated with the FTP server must have READ access to them.

5. (Optional) If the daemon address space will be configured to run as nonswappable, provide at least READ access to the FACILITY class resource BPX.STOR.SWAP.

6. Set up security for the FTP server.
   See “Security for the FTP server” on page 640 for information about setting up security.

7. (Optional) Define environment variables.
   See “Defining environment variables for the FTP server (optional)” on page 647 for information about defining environment variables for the FTP server.

   **Results**

   When you are done, you should be able to start the FTPD catalogued procedure with no errors. If you receive errors, then ensure that you have completed all the steps correctly.

   See SEZAINST(EZARACF) for more information about SAF resource requirements needed for FTP.

   **Restriction:** The Language Environment runtime option NATLANG(JPN) is not supported. If you specified NATLANG(JPN) as a Language Environment runtime option, then you need to specify PARM='NATLANG(ENU)' in the FTPD cataloged procedure to override the runtime option for FTP.

   **Security for the FTP server**

   To provide security for the FTP server, you must perform the following tasks:

   1. (Optional) Activate and define the SERVAUTH class (see “(Optional) Steps for activating and defining the SERVAUTH class” on page 641).

   2. Set up security for the FTP server (see “Steps for setting up security for your FTP server” on page 641).

   3. Provide and control user access to the FTP server (see “Steps for controlling user access to the FTP server” on page 642).

   4. Set up a port of entry for users of the FTP server (see “Steps for setting up a port of entry for users of the FTP server” on page 643).
5. Provide and control user access to the z/OS UNIX file system (see “(Optional) Steps for controlling user access to the z/OS UNIX file system” on page 644).

6. Prevent exploitation of your FTP server (see “Preventing exploitation of your FTP server” on page 645).

7. (Optional) Assign password phrases to user IDs that are used to log in to the FTP server (see “(Optional) Assigning password phrases to user IDs that are used to log in to the FTP server” on page 646).

FTP uses resource profiles in the System Authorization Facility (SAF) SERVAUTH class to control access to certain facilities and servers. When access to a resource is controlled by a profile in the SERVAUTH class, you must activate and RACLIST the SERVAUTH class. You do not have to use the SERVAUTH class, but when a profile is defined in that class, all FTP users who require access to it must be permitted to it.

For more information, see z/OS UNIX System Services Planning and z/OS Security Server RACF Security Administrator's Guide. For more information about network access security zones, see “Network access control” on page 136. If you are planning to implement a multilevel security environment on your z/OS system, see Chapter 4, “Preparing for IP networking in a multilevel secure environment,” on page 177.

(Optional) Steps for activating and defining the SERVAUTH class
FTP uses resource profiles in the System Authorization Facility (SAF) SERVAUTH class to control access to certain facilities and servers.

Before you begin
You need to know which resource profiles you want to define. You need to install and start your security product.

Procedure
Perform the following steps to activate and RACLIST the SERVAUTH class, if you have not already done so:

1. Issue the following command from a RACF special user to activate the SERVAUTH class:

   ```
   SETROPTS CLASSACT (SERVAUTH)
   ```

   **Requirement:** If you change the SERVAUTH class after you activate it, you must refresh the class. Changes include, but are not limited to, adding a resource profile to the SERVAUTH class or changing access to a profile in the SERVAUTH class. To refresh the class, issue the following command from a RACF special user:

   ```
   SETROPTS RACLIST (SERVAUTH) REFRESH
   ```

2. Issue the following command from a RACF special user to RACLIST the SERVAUTH class:

   ```
   SETROPTS RACLIST (SERVAUTH)
   ```

Steps for setting up security for your FTP server
You need to provide appropriate access to the user ID that is associated with the FTP daemon.

Before you begin
You need to know the user ID that is associated with the FTP daemon and how TCP/IP is configured for security. You should also know the resource profiles that are in the SAF classes.

Procedure
To set up security for your FTP server, perform one or more of the following tasks:

- If the SERVAUTH class is activated and a profile is defined for the `EZB.STACKACCESS.mvsname.tcpname` resource, you must grant the user ID that is associated with the FTP daemon READ access to the profile.
• If the SAF class APPL is activated and the OMVSAPPL resource profile is defined, grant the user ID that is associated with the FTP daemon READ access to the OMVSAPPL resource profile.

For more information on defining the OMVSAPPL profile, see z/OS UNIX System Services Planning.

• If the SAF class APPL is activated and you have a resource profile defined in that class that matches the job name of the address space that the FTP server starts when a user logs into FTP, a user ID should have READ access to that resource profile.

• The FTP daemon listening port should be reserved for the FTPD job by a PORT statement in the TCPIP PROFILE. If the PORT statement for the FTPD port is protected with the SAF keyword, you must define a SERVAUTH profile for the EZB.PORTACCESS.sysname.tcpname.SAFkeyword resource. The user ID associated with the FTP daemon must have READ access to that resource.

• If your IP network is configured to use named security zones, grant the user ID that is associated with the FTP daemon READ access to the security zone that maps its bind address (0.0.0.0/32 for INADDR_ANY or ::/128 for the IPv6 unspecified address, in6addr_any), unless these addresses are overridden by the PORT statement in the TCP/IP profile.

Results
You know you are done when you can start the FTP server without receiving an error.

Steps for controlling user access to the FTP server
Every user that logs in to your FTP server requires access to that server. Use these steps to provide and control user access to your server.

Before you begin
You need to know which users you want to allow to log in to your FTP server. You need to know whether your IP network is configured to use named security zones.

Procedure
Perform the following steps to control user access to the FTP server:

1. Provide each user who is going to log in to the FTP server with a z/OS UNIX UID.
   You can either provide a UID to the user, or the user can use the default UNIX UID.

2. If your IP network is configured to use named security zones, each defined security zone has a SERVAUTH profile for the resource named EZB.NETACCESS.sysname.tcpname.zonename. If the client IP address is mapped into a network access security zone, grant each login user ID READ access to the SERVAUTH profile that corresponds to the security zone.
   For more information about security zones, see “Network access control” on page 136.

3. Do one or more of the following items to allow only certain users to log in to the FTP server:
   • Code an FTCHKPWD user exit routine to allow or deny access to users, based on user ID.
     For more information about user exits, see FTP server user exits in z/OS Communications Server: IP Configuration Reference and “Configuring the optional FTP user exits” on page 683.
   • Use the SERVAUTH resource profile that FTP uses for TLS level 3 authentication to control which users can log in to FTP:
     a. Define a profile in the SERVAUTH class for the FTP port.
     b. Grant at least READ access to the profile to the users that you want to permit to log in to FTP.

     For example, if your security product is RACF, your FTP port is port 21, and the profile that you defined is EZB.FTP.*.*.PORT21, issue the following command to grant the user ID FTPUSER access to the profile:
     ```shell
     PERMIT EZB.FTP.*.*.PORT21 CL(SERVAUTH) ID(FTPUSER)
     ```

c. Code VERIFYUSER TRUE in the server’s FTP.DATA file.

FTP verifies the user’s access to the profile for every session, whether or not that session is secured. TLS-secured sessions are also verified, even when level 3 authentication has not been requested.

4. (Optional) Set up transport layer security (TLS) support or Kerberos support for the FTP server.

The FTP server supports TLS. TLS enables secure file transfer by providing data privacy, message authentication, and message integrity services for data sent and received using the FTP control and data connections. For information about setting up TLS support for the FTP server, see “Customizing Transport Layer Security and Kerberos security” on page 659.

You can use the Generic Security Service Application Programming Interface (GSSAPI) to authenticate FTP clients to FTP servers. For more information about setting up GSS support for the FTP server, see “Customizing Transport Layer Security and Kerberos security” on page 659.

Results

When you are finished, only certain users will be able to log in to your FTP server.

Steps for setting up a port of entry for users of the FTP server

The port of entry is the origin of work for the FTP server. You must establish a port of entry for each user who logs in to your FTP server.

Before you begin

You must know:

• The IP addresses of the clients that are to log in to your FTP server
• Whether your connection partners are in a network access security zone
• Whether your RACF SETROPTS options are TERMINAL(READ) or TERMINAL(NONE)

For IPv4 connection partners, you can establish either terminal access or SERVAUTH access. IPv6 connection partners must use SERVAUTH access, which is established automatically for them.

Procedure

Perform the following steps to set up the port of entry for IPv4 and IPv6 users of the FTP server.

• To establish terminal access for IPv4 connection partners, take one of the following actions:
  - If your RACF SETROPTS options are TERMINAL(NONE):
    1. Define profiles for the IP addresses that you want to permit to your system in the TERMINAL class.

       Translate all the IP addresses of any clients that connect to the FTP server to an 8-byte hexadecimal character strings that contain an IPv4 address. Add the strings to the TERMINAL class.

       For example, the IP address 163.97.227.17 is translated to A361E311. To allow all addresses in the 163.97.227.17 subnet, code the following statement:

       ```
       RDEFINE TERMINAL A361E3* UACC(READ)
       ```

    2. Ensure that login user IDs have READ access to the TERMINAL profile that includes their client system IP address.
  - If your RACF SETROPTS options are TERMINAL(READ), then all terminals are allowed access to your system and you do not need to add extra resource definitions to your RACF database.

• To establish SERVAUTH access, instead of terminal access, for IPv4 connection partners, specify PORTOFENTRY4 SERVAUTH in the FTP.DATA file. The FTP server will use the UNIX System Services _poe() service to identify the control socket as the port of entry.
• To establish SERVAUTH access for IPv6 connection partners, you do not need to do anything; IPv6 connection partners automatically establish SERVAUTH access. If the IPv6 connection partner is not in a network access security zone, the _poe() service does not pass a port of entry resource name and the port of entry is not checked. For information about network access security zones, see "Network access control" on page 136.

For IPv4 and IPv6 users with either terminal or SERVAUTH access, you can optionally restrict access to DATASET resources during the login session by adding WHEN(TERMINAL=...) or WHEN(SERVAUTH=...) conditions to DATASET resource profiles in RACF.

Results
When you are finished, access to the FTP server is controlled based on the client's port of entry.

(Optional) Steps for controlling user access to the z/OS UNIX file system
FTP uses the resource profile EZB.FTP.sysname.ftpd daemonname.ACCESS.HFS in the SAF SERVAUTH class to control access to the z/OS UNIX file system. If you do not control access to this profile, then all users can access your z/OS UNIX file system.

Before you begin
If the FTP.DATA file for the server specifies STARTDIRECTORY HFS and the user is not permitted to the SERVAUTH class profile, FTP makes the TSO user ID the starting directory.

You must have the authority to issue the necessary RACF commands.

Procedure
Perform the following steps to control access to the z/OS UNIX file system:

1. Define the profile for the FTP user access to the z/OS UNIX file system.
   The profile has the following form:

   RDEFINE SERVAUTH EZB.FTP.sysname.ftpd daemonname.ACCESS.HFS

   For example, the profile name for FTP daemon FTPD running on system MVSA is the following name:

   EZB.FTP.MVSA.FTPD.ACCESS.HFS

   Tip: The profile name can contain wildcard values as allowed by the security product. All security-product rules (for example wildcards, PROTECTALL, and so on) apply. For example, if all systems will use the same access list and RACF generic profile checking is active for the SERVAUTH class, you could use the following profile name:

   EZB.FTP.*.FTPD.ACCESS.HFS

2. Permit the user IDs that require access to the z/OS UNIX file system to the profile:

   PERMIT EZB.FTP.sysname.ftpd daemonname.ACCESS.HFS CL(SERVAUTH) ID(ftpuser)

3. Issue the following command to activate the RACF SERVAUTH class, if it is not already activated:

   SETROPTS CLASSACT (SERVAUTH)

4. Take one of the following actions:
   • RACLIST the SERVAUTH class, if this is a new profile:
     SETROPTS RACLIST (SERVAUTH)
   • Refresh the SERVAUTH class, if you have changed an existing profile:
     SETROPTS RACLIST (SERVAUTH) REFRESH
Results
When you are finished, only certain users will be able to access the z/OS UNIX file system.

Preventing exploitation of your FTP server
Your FTP server can be used by a client for disruptive purposes. A client can use your server to send random data to other servers, or a client can request that your server be the passive server in a three-way transfer.

Any FTP client that is in PROXY mode with your FTP server can establish a data connection to any server that is listening to a port. This situation could be very disruptive to that server, because the client could then send a very large amount of unexpected data to it. Any malicious FTP client can attack or disrupt the server in a normal server-to-client connection by making the FTP server send a large amount of data to another application server that is listening to a specific port. Because the client itself is not sending the disruptive data, it is difficult to identify the client that is causing the problem. Use the PORTCOMMAND, PORTCOMMANDPORT and PORTCOMMANDIPADDR statements in FTP.DATA to prevent your server from being used in this way.

Table 31. PORTCOMMAND scenarios

<table>
<thead>
<tr>
<th>When you want your server to...</th>
<th>Code the following statements in the server's FTP.DATA</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Reject all PORT or EPRT commands</td>
<td>PORTCOMMAND REJECT</td>
<td>If you disable the PORT or EPRT commands, then you prevent your server from being used to send random data to other servers. However, your server loses some ability to transfer data in PROXY mode. If a client sends a PORT or EPRT command to your server to set up a proxy transfer, your server will reject the command and the proxy transfer will fail. If your client is not firewall friendly, and it does not implement the default port number and IP address for data transfer, that client cannot transfer files to and from your server.</td>
</tr>
<tr>
<td>Reject all PORT or EPRT commands that specify well-known ports (port numbers less than 1024)</td>
<td>PORTCOMMANDPORT NOLOWPORTS</td>
<td>When you specify this combination, your server cannot be used to send random data to servers listening on well-known ports. However, a rogue client can use your server to send random data to servers listening on other ports. The server still supports data transfer in PROXY mode.</td>
</tr>
<tr>
<td>Reject all PORT or EPRT commands that specify an IP address other than the client's own IP address.</td>
<td>PORTCOMMANDIPADDR NOREDIRECT</td>
<td>When you specify this combination, a client can request data transfer in PROXY mode only between your server and a server on its own IP address. Transfers between client and server are not affected.</td>
</tr>
</tbody>
</table>
Table 31. PORTCOMMAND scenarios (continued)

<table>
<thead>
<tr>
<th>When you want your server to...</th>
<th>Code the following statements in the server's FTP.DATA</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Reject all PORT or EPRT commands that specify an IP address other than the client's own IP address or port numbers that are well known.</td>
<td>PORTCOMMANDPORT NOLOWPORTS PORTCOMMANDIPADDR NOREDIRECT</td>
<td>When you specify this combination, a client can request data transfer in PROXY mode only between your server and a server that is on its own IP address; the port numbers cannot be well known. The client cannot use PROXY mode to send random data to a server that is on its own IP address and listening to a well-known port.</td>
</tr>
</tbody>
</table>

Your FTP server can also be used as a passive server in a three-way transfer. When a client sends a PASV or EPSV command to the server, the server opens a listening data socket. This socket is similar to the listening socket associated with the well-known port, in the sense that any application that knows its IP address and port number can connect to it (not just the client that sent the PASV or EPSV command). The client can exploit this situation to initiate a three-way data transfer, which is a data transfer between two servers. The client sends PASV to one server followed by PORT to the other. The client sets the PORT command IP address and port number to the information it gets from the PASV reply, and the second server connects to the IP address and port number specified in the PORT command, connecting the two servers. The next data transfer command causes data to move directly between the two servers. The client can also use the EPSV and EPRT commands to set up the three-way data transfer.

Three-way transfers are supported functions in the FTP protocol, but you might not want to allow your server to participate in three-way transfers. To prevent your server from being the passive server (the server that receives the PASV or EPSV command) in a three-way data transfer, code PASSIVEDATACONN NOREDIRECT in the server's FTP.DATA file. This directs the server to verify that the data connection comes from the IP address where the original FTP client is (the client that sent the PASV or EPSV command). If that is not where the data connection originates, the server closes the data socket and the next data transfer command fails.

To completely disallow the use of your FTP server in three-way transfers, code the PASSIVEDATACONN statement as described in the preceding paragraph, and the PORTCOMMANDIPADDR NOREDIRECT statement or PORTCOMMAND REJECT statement described in Table 31 on page 645.

(Optional) Assigning password phrases to user IDs that are used to log in to the FTP server

You can enable users to log in to the FTP server with password phrases by assigning password phrases to the user IDs that are used to log in to the FTP server.

Guideline: Use the RACF ALTUSER command to assign a password phrase to a user ID. See assigning password phrases in the z/OS Security Server RACF Security Administrator’s Guide for more information.

Rules:
- Do not assign a character or combination of characters to a password phrase that your FTP clients cannot support.
- The maximum length of a password phrase is 100 characters.

Tips:
- Use alphanumeric characters to create password phrases to minimize translation problems when the client and server are using different ASCII code pages.
- If you plan to use the z/OS FTP client in batch mode, the password phrase and optional user data must fit on a single line of the batch file.

Results:
When you assign a password phrase to a user ID, a user can log in with that user ID by using either the password or the password phrase.

A user can change the password phrase when they log in to FTP.

Restrictions:

- The password phrase that a user enters to log in to the z/OS FTP server has restrictions beyond those that are enforced by your security product and those that are enforced by the optional ICHPWX11 user exit. The password phrase must not contain the following characters that have special meaning to the z/OS FTP server:
  - NULL (X'00')
  - Slash (/)
  - Colon (:
  - Carriage return (<cr>)
  - Line feed (<lf>)
  - Interpret as command (<IAC> or X'FF')
  - Telnet command characters (X'FB' - X'FE')

The z/OS FTP server translates all passwords that it receives during a session into EBCDIC before it passes them to the security product and to the FTCHKPWD exit routine.

- A user will not be able to log in to the z/OS FTP server using a password phrase if you assign a character to the password phrase that the server cannot translate from ASCII or UTF-8 to EBCDIC. The user will also not be able to log in if you assign a character that the server translates into an EBCDIC character that is different than the character that you assigned. Untranslatable characters and inconsistent translations can occur if the client and server are using different code pages, or if the character is outside the normal range of printable characters.

- The z/OS FTP server supports quotation marks in password phrases, but your FTP client might not support the use of quotation marks in password phrases.

- The password phrase must not contain leading blanks or trailing blanks.

- The maximum length of a password phrase is 100 characters.

- When you configure the z/OS FTP server for anonymous FTP, the following restrictions apply:
  - You cannot specify a password phrase instead of a password as an FTP daemon start option.
  - You cannot code a password phrase instead of a password on the ANONYMOUS statement in FTP.DATA.

If the server is configured to prompt anonymous users for a password, the user can log in with either the password or the password phrase that is assigned to the anonymous user ID.

Defining environment variables for the FTP server (optional)

The FTP server optionally uses environment variables to identify the translate table data sets to be used for the control and data connections. The FTP server uses the following environment variables to override a default naming convention.

Using _FTPXLATE_name for translation

In your FTP.DATA file, you can use the CCXLATE or XLATE statements to specify a name that corresponds to a particular data set that is to be used for the initial translate tables for the control or data connections.

Rules:

- CCXLATE is ignored if EXTENSIONS UTF-8 or CTRLCONN is coded in FTP.DATA.
- XLATE is ignored if SBDATACONN is coded in FTP.DATA.

FTP searches for an environment variable defined as _FTPXLATE_name=fully_qualified_dsn with the following specifications:
The XLATE or CCXLATE parameter value you coded in FTP.DATA. You can code 1 to 8 alphabetic or numeric characters.

fully qualified dsn
A fully qualified MVS data set name or z/OS UNIX file name.

Requirements:

- You must use uppercase letters for the name value of the _FTPXLATE_name environment variable.
- The name value must follow the rules for an MVS data set qualifier if you do not define the _FTPXLATE_name environment variable.

FTP identifies the data set corresponding to the name value:

- If the environment variable is defined, FTP uses the data set name that is defined by the environment variable.
- If the environment variable is not defined, FTP uses the data set name hlq.name.TCPXLBIN.

You can also issue the SITE XLATE= command from any client to set the translate tables for the data connection for that particular FTP session. The FTP server searches for an environment variable called _FTPXLATE_name and uses the data set name that _FTPXLATE_name defines. If the _FTPXLATE_name environment variable does not exist, the server searches for a data set called hlq.name.TCPXLBIN.

Using TZ and other UNIX environment variables

Use the ENVAR runtime option in your FTPD start procedure to set environment variables for the FTP server. For information about using the ENVAR runtime option to set environment variables, see z/OS XL C/C++ Programming Guide. The following example shows how to use ENVAR to specify environment variables in your FTPD started procedure:

```plaintext
//FTPD   PROC MODULE='FTPD',PARMS=''
//FTPD   EXEC PGM=&MODULE,REGION=4096K,TIME=NOLIMIT,
//       PARM=("POSIX(ON) ALL31(ON)",
//              "ENVAR("TZ=EST")/&PARMS")
```

Using _BPX_JOBNAME for similar job names

If you want all FTP forked tasks to have similar job names, set the _BPX_JOBNAME environment variable. For example, for WorkLoad Manager (WLM), accounting, and isolation of syslogd messages, you might not want each FTP user that is logged in to have its user ID for a job name.

The following example shows how to use the _BPX_JOBNAME environment variable to assign the job name FTPD to all FTP forked tasks:

```plaintext
//FTPD   PROC MODULE='FTPD',PARMS=''
//FTPD   EXEC PGM=&MODULE,REGION=4096K,TIME=NOLIMIT,
//       PARM=("POSIX(ON) ALL31(ON)",
//              "ENVAR("_BPX_JOBNAME=FTPD")",
//              "TZ=EST")/&PARMS')
```

Requirement: If you activate the SAF class APPL and define a resource profile in that class for the job name resource that you specify with the _BPX_JOBNAME environment variable, you must grant user IDs that log in to FTP at least READ access to that resource.

Using _BPXK_SETIBMOPT_TRANSPORT for an affinity to a specific stack

If you want to ensure that FTP has an affinity to a particular TCP/IP stack, use the _BPXK_SETIBMOPT_TRANSPORT environment variable. For more information, see “Generic server versus server with affinity for a specific transport provider” on page 46.

The following example shows how to use the _BPXK_SETIBMOPT_TRANSPORT environment variable to set the FTP server to have an affinity to TCPIPOE:

```plaintext
//FTPD   PROC MODULE='FTPD',PARMS=''
//FTPD   EXEC PGM=&MODULE,REGION=4096K,TIME=NOLIMIT,
```
Configuring FTP with multiple TCP/IP stacks

Prior to configuring the FTP server with multiple TCP/IP stacks, review “Considerations for multiple instances of TCP/IP” on page 45.

The FTP server can be configured as a server with affinity to a specific transport provider or as a generic server.

To configure the FTP server to have affinity to a specific transport provider, take the following actions:

• Code the _BPXK_SETIBMOPT_TRANSPORT keyword in the FTP cataloged procedure. The example below sets the FTP server to have an affinity to TCPIPOE.

```
//FTPD   PROC MODULE='FTPD',PARMS=''
//FTPD   EXEC PGM=&MODULE,REGION=4096K,TIME=NOLIMIT,
//      PARM=('POSIX(ON) ALL31(ON)',
//           'ENVAR("_BPXK_SETIBMOPT_TRANSPORT=TCPIPOE"',
//           "TZ=EST")/&PARMS')
```

• Reserve ports 21 and 20 for the FTP server in PROFILE.TCPIP as follows:

```
PORT
  21 TCP FTPD1          ; FTP server control port
  20 TCP OMVS NOAUTOLOG ; FTP server data port
```

To configure the FTP server as a generic server, reserve ports 21 and 20 for the FTP server in PROFILE.TCPIP on all transport providers. The FTP server will detect when new transport providers are activated and attempt to bind to port 21. If this port is not reserved for the FTP server, the FTP server will end with the following message:

```
EZYFT13E bind error : EDC5111I Permission denied
```

Configuring TCPIP.DATA for FTP

The following five statements are used by the FTP server:

- **DATASETPREFIX**: Specifies HLQ for dynamic allocation
- **DOMAINORIGIN**: Specifies the domain name to be appended to host name
- **HOSTNAME**: Specifies the TCP host name
- **LOADDBCSTABLES**: Specifies the DBCS tables used by the client and server
- **MESSAGECASE**: Specifies the case that messages should be displayed in

See Chapter 2, “IP configuration overview,” on page 11 for information about TCPIP.DATA or see z/OS Communications Server: IP Configuration Reference for information about these statements.

Configuring FTP.DATA

The FTP.DATA data set is optional. The FTP daemon looks for this data set during initialization, using the first file it finds in the following search order:
1. A data set specified by the //SYSFTPD DD statement
2. ftpserve_job_name.FTP.DATA
3. /etc/ftp.data
4. SYS1.TCPPARMS(FTPDATA)
5. hlq.FTP.DATA data set

It is not necessary to include all statements in the FTP.DATA data set. Include the statements only if the default value is not what you want, because the default will be used for any statement not included in the FTP.DATA data set.

To pick up changes made in the FTP.DATA data set, the FTP server must be stopped and restarted. Some FTP server parameters can be changed during an FTP session by the client issuing the SITE subcommand. See z/OS Communications Server: IP User’s Guide and Commands for more information. The FTP client has an FTP.DATA data set which can also be used to change the defaults for the FTP client local site parameters. See the z/OS Communications Server: IP User’s Guide and Commands for more information about using the FTP.DATA data set for the FTP client local site parameters.

**Optionally configuring user-level server options using FTPS.RC**

The default values for the site parameters are coded in the server FTP.DATA. These SITE defaults apply to all login sessions to the server. You can customize settings for a specific user or group of users by creating an FTPS.RC configuration data set containing FTP commands specific to that login session. This file may contain a series of CWD and SITE commands. See z/OS Communications Server: IP User's Guide and Commands for information about these commands.

The FTP server uses the following search order to find the MVS data set or z/OS UNIX file:

1. tso_prefix.FTPS.RC
2. userid.FTPS.RC
3. $HOME/ftps.rc

**Data set attributes**

Data set attributes play a significant role in FTP performance. If your environment permits, tune both BLOCKSIZE and LRECL according to the following recommendations:

- Use half a track as the block size.
- For IBM 3380 DASD, use 23424 as the block size with an LRECL of 64 bytes.
- For IBM 3390 DASD or IBM9334, use 27968 as the block size with an LRECL of 64 bytes.
- Use FB as the data set allocation format.
- Use cached DASD controllers.
- If your environment permits, use a preallocated data set for FTP transfers into MVS.

The following configuration data statements apply to FTP server's allocation of data sets.

- AUTOMOUNT
- AUTORECALL
- BLKSIZE
- BUFNO
- CONDDISP
- DATACLASS
- DCBDSN
- DIRECTORY
- DSNTYPE
- EATTR
• LRECL
• MGMTCLASS
• MIGRATEVOL
• PDSTYPE
• PRIMARY
• RECFM
• RETPD
• SECONDARY
• SPACETYPE
• STORCLASS
• UCOUNT
• UMASK
• UNITNAME
• VCOUNT
• VOLUME

See z/OS Communications Server: IP Configuration Reference for more detailed information about these keywords.

Some of these allocation variables might provide duplicate information. FTP passes all variables that are specified to the z/OS dynamic allocation function to determine which of the specifications take precedence, except for the following exceptions:

• If the data set organization is physical sequential, directory blocks are not sent.
• If neither primary nor secondary space quantities are specified, the allocation units value is not sent.

For example, the model DCB (DCBDSN) might have a record format (RECFM) that differs from the record format specified by a data class and from the one explicitly specified by the client. The order of precedence for dynamic allocation variables are as follows:

1. Any FTP.DATA statements or SITE parameters explicitly specified or in effect by default.
2. Any attributes picked up from the model DCB and not otherwise explicitly specified.
3. Any attributes picked up from the data class and not previously derived from 1 and 2 above.
4. Any system allocation defaults.

Specifying attributes for new MVS data sets

When allocating new data sets, there are two methods you can use to specify the data set attributes. You can customize the data set attributes for your login session using the SITE command, or you can configure the data set attributes for logging in to your server using statements in FTP.DATA. Or, if your system programmer has used the Storage Management System to group together default attributes into named classes, you can specify those class names on the DATACLASS, STORCLASS, and MGMTCLASS statements.

Dynamic allocation

The FTP server allows a client program to dynamically allocate a new physical sequential data set, a partitioned data set (PDS), or a partitioned data set extended (PDSE), for the purpose of transferring data to be written to that data set. The following optional allocation variables can be used to override and turn off the defaults that affect the allocation of the data set.

Variable
FTP.DATA statement
allocation units
SPACETYPE
Some of these allocation variables might provide duplicate information. For example, the model DCB might have a record format (RECFM) that differs from the record format specified by a data class and from the one explicitly specified by the client. FTP passes all variables that are specified to dynamic allocation and lets it determine which of the specifications take precedence. The following list describes the exceptions to that policy:

- If neither the primary nor secondary space quantity is specified, the allocation units value is not sent.
- If the data set organization is physical sequential, directory blocks specification is not sent.
- Otherwise, all variables are sent to dynamic allocation where the order of precedence is:
  1. Any FTP.DATA statements or SITE parameters explicitly specified or specified by default
2. Any attributes picked up from the model DCB and not otherwise explicitly specified
3. Any attributes picked up from the data class and not previously derived from 1 or 2
4. Any allocation defaults

**Storage Management Subsystem**

You can specify one or more of the following Storage Management Subsystem (SMS) classes to manage characteristics that are associated with or assigned to data sets.

- Data class is an SMS construct that an installation can define to control data set allocation attributes used by SMS for the creation of data sets. An installation can override all or part of an SMS DATA CLASS definition by using FTP.DATA statements. Note that there is an order of precedence for dynamic allocation. (See “Data set attributes” on page 650 for more information on the precedence.) The fields listed are available attributes that serve as a template for allocation. Each is optional and is overridden by any explicit specification of FTP-allocation variables. Except for the DSNTYPE and EATTR fields, the listed variables can be overridden by a model DCB (DCBDSN).

**Variable FTP.DATA statement**

| directory blocks | DIRECTORY |
| data set name type | DSNTYPE |
| extended attributes | EATTR |
| logical record length | LRECL |
| primary space | PRIMARY |
| record format | RECFM |
| retention period | RETPD |
| secondary space | SECONDARY |
| pds type | PDSTYPE |

**Note:** If either primary or secondary space is explicitly specified, the primary and secondary values from data class are not used.

- Management class (MGMTCLASS) is an SMS construct that determines DFHSM action for data set retention, migration, backup, and release of allocated but unused space. Management class replaces and expands attributes that otherwise would be specified. That is, management class might override any other specification of retention period.
- Storage class (STORCLASS) is a list of storage performance and availability services requests for an SMS-managed data set that SMS attempts to honor when selecting a volume or volumes for the data set. It might conflict with an explicit specification of volume and unit. If storage class is used, volume and unit should not be specified.

**Translation of data**

Selecting an appropriate translate table for conversion of data from host to network format, and from network to host format, will ensure that data read from or written to the z/OS system are in correct format. The following statements apply to translation of data for the FTP server. See z/OS Communications Server: IP Configuration Reference for more information on these statements. The statements are:
• ASATRANS
• CTRLCONN
• DBSUB
• ENCODING
• EXTENSIONS UTF8
• MBDATACONN
• MBSENDEOL
• MBREQUIRELASTEOL
• SBDATACONN
• SBSENDEOL
• SBSUB
• SBSUBCHAR
• UCHOSTCS
• UCSSUB
• UCSTRUNC
• UNICODEFILESYSTEMBOM

z/OS UNIX named pipes

FTP can transfer data to and from z/OS UNIX System Services named pipes. The following statements apply to the creation of named pipes:

• UMASK
• UNIXFILETYPE

The following statements apply to the transfer of data to and from named pipes:

• CONDDISP
• FIFOIOTIME
• FIFOOPENTIME

For more information about these FTP.DATA data set statements, see z/OS Communications Server: IP Configuration Reference. For information about using z/OS UNIX System Services named pipes, see z/OS Communications Server: IP User's Guide and Commands.

FTP code page conversion

Code page conversion must be performed for:

• FTP commands and replies sent over the control connection
• Data transferred over the data connection

FTP uses the iconv function to establish ASCII-to-EBCDIC and EBCDIC-to-ASCII translate tables for the control connection. The default network transfer code page for the control connection is 7-bit ASCII. In addition, FTP maintains support for the use of translate tables by the CONVXLAT utility. After a user has logged in, a SITE subcommand can be used to change the code page being used on the control connection.

FTP uses the iconv function to establish network transfer to file system and file system to network transfer translate tables for the data connection. In addition, FTP maintains support for the use of translate tables by the CONVXLAT utility.

Note: Using iconv conversion to retrieve EBCDIC data that was created with CONVXLAT-generated conversion tables could result in data corruption due to possible conversion table differences.
After a user has logged in, SITE and LOCSITE subcommands can be issued to change the translation tables being used for single-byte translation.

**Code page conversions for the control connection**

For the control connection, FTP generally uses ASCII for the network code page, as specified in the FTP RFCs. For the host/ASCII conversion for the control connection, FTP uses either iconv() or the support for single-byte translation tables. However, when EXTENSIONS UTF8 is coded in FTP.DATA, FTP starts the connection in 7-bit ASCII and negotiates a switch to UTF-8 encoding of the control connection, as described in RFC 2640. FTP uses iconv() for the host/UTF-8 conversion.

**Priority**

The priority for establishing the conversion tables used for the control connection is:

1. FTP start parameter (FTP client only)
2. EXTENSIONS UTF8 coded in FTP.DATA
3. CTRLCONN or CCXLATE keyword in FTP.DATA
4. Search order used to locate a TCPXLBIN data set:
   a. Original jobname.SRVRFTP.TCPXLBIN
   b. hlq.SRVRFTP.TCPXLBIN
   c. Original jobname.STANDARD.TCPXLBIN
   d. hlq.STANDARD.TCPXLBIN
5. 7–bit ASCII
6. Internal (hard-coded) 7–bit tables

**Code page conversions for the data connection**

For the transfer of data on the data connection, FTP supports:

- All single-byte conversions available through iconv. For example, iconv supports conversions between IBM-1047 and IBM-850, so conversions between IBM-1047 and IBM-850 are available for data transfer.
- UNICODE conversions available through iconv: UTF-8, UTF-16, UTF-16BE, and UTF-16LE for network transfer, and UTF-8 and UTF-16 for file storage.
- Multibyte conversions for the Chinese standard GB18030 using code page IBM-5488 with code page IBM-1388 or UTF-8, as well as certain double-byte character set (DBCS) code page pairs that are equivalent to supported DBCS languages.
- Both single-byte and double-byte data conversions are supported with the translate tables provided with TCP/IP or generated by the CONVXLAT utility.

**Priority for single-byte conversions**

How to build single-byte translate tables for converting network transfer data and file system data is determined by the following priority:

- SYSFTSX DD statement in the startup procedure, where the named data connection is CONVXLAT-generated translate tables. The data set can be an MVS data set or a z/OS UNIX file.
- SBDATACONN or XLATE keyword in FTP.DATA.
- Search order to locate a TCPXLBIN data set, where the MVS data set contains CONVXLAT-generated translate tables:
  1. Original jobname.SRVRFTP.TCPXLBIN
  2. hlq.SRVRFTP.TCPXLBIN
  3. Original jobname.STANDARD.TCPXLBIN
  4. hlq.STANDARD.TCPXLBIN
• The same conversions established for the control connection.

**Multibyte character sets (MBCS) support**

MBCS support in the FTP server is provided for the following code page pairs:

<table>
<thead>
<tr>
<th>Support for</th>
<th>TYPE command</th>
<th>File system code page</th>
<th>Network transfer code page</th>
</tr>
</thead>
<tbody>
<tr>
<td>Chinese standard</td>
<td>Not applicable</td>
<td>IBM-1388 or UTF-8</td>
<td>IBM-5488</td>
</tr>
<tr>
<td>GB18030</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>BIG5</td>
<td>TYPE B 8</td>
<td>IBM-937</td>
<td>IBM-950 or BIG5</td>
</tr>
<tr>
<td>EUCKANJi</td>
<td>TYPE B 2</td>
<td>IBM-930</td>
<td>IBM-eucJP</td>
</tr>
<tr>
<td>JIS78KJ (JISROMAN)</td>

<td>IBM-930 or IBM-939</td>
<td>IBM-932 or IBM-eucJC</td>
</tr>
<tr>
<td>TCHINESE</td>
<td>TYPE B 7</td>
<td>IBM-937</td>
<td>IBM-948</td>
</tr>
<tr>
<td>UNICODE</td>
<td>Not applicable</td>
<td>UTF-8, UTF-16</td>
<td>UTF-8, UTF-16, UTF-16BE, and UTF-16LE</td>
</tr>
</tbody>
</table>

**Rules:**

• ENCODING must be specified as MBCS, either in FTP.DATA or on a SITE command.
• The data type must be ASCII.
• The file structure must be FILE (not RECORD), and the transfer mode must be STREAM (not BLOCK or COMPRESS).
• The FTP file type must be SEQ (not JES or SQL).
• If the file is transferred to or from an MVS data set, the record format of the data set must be V, VB, or U.
• If a file is transferred outbound and is an MVS data set with record format V or VB, the request for RDWs is not allowed.
• Translation of ASA or machine control characters is not allowed.
• MBCS can be used as a migration path for the DBCS languages listed that have an associated TYPE B x command.

**Restriction:** The DBCS languages can be migrated to the MBCS support only if they do not use the following parameters on the TYPE B x command:

**S A**
SOSI ASCII characters X'1E' and X'1F' in the ASCII data stream

**S E**
SOSI EBCDIC characters X'0E' and X'0F' in the ASCII data stream

**S S**
SOSI SPACE characters X'20' and X'20' in the ASCII data stream

**N**
No SOSI characters in the ASCII data stream and none written to the file system.
Master catalog access

FTF uses the IGGCSI00 function to request catalog processing. This accesses both the user and master catalog. Users require READ access to the master catalog as well as their own user catalog.

Customizing FTP message catalogs

FTP messages and replies are contained in two z/OS UNIX message catalogs as follows:

- ftpdmsg.cat
  Contains messages that the FTP daemon, server, and client issue.
- ftpdrply.cat
  Contains replies that the server sends to the client.

If messages in either of these catalogs need to be modified, the timestamp that is contained in the shipped level of the FTP catalog must be preserved in the modified catalog.

This timestamp is included within and is unique to each catalog. When FTP (client or daemon) is started, FTP verifies that this timestamp matches the timestamp that it expects. This prevents FTP from presenting the wrong message when the z/OS UNIX message catalogs and FTP are not synchronized.

When you apply a service update to FTP load modules that requires a service update to a catalog, you must install both at the same time. Otherwise, FTP will report an error and use default messages instead of messages from the catalog.

If you are using a modified FTP catalog, the catalog that matches the service level of FTP load modules needs to be updated with your local modifications, and the timestamp of the catalog must be preserved.

Steps for creating a message catalog from the shipped catalog and preserving its timestamp

After using these steps you can then update the file with your local modifications and create a new FTP catalog with the preserved timestamp. Perform all of these steps from the z/OS UNIX shell; the commands indicated are z/OS UNIX commands.

Before you begin

This example assumes that the FTP code and catalog are at the correct levels and that only local customization to the catalog is to be performed. Also, if you customize a catalog, IBM Service personnel might require that you use the shipped level of the catalog to recreate and diagnose a reported problem.

Procedure

Perform the following steps to create a file from the shipped catalog and preserve its timestamp:

1. Copy the official z/OS UNIX catalog that is shipped with the release or service to a backup file.
   
```bash
cp /usr/lpp/tcpip/lib/nls/msg/C/ftpdmsg.cat /tmp/ftpdmsg.cat.backup
```

2. Using the `dspcat` command, convert a copy of the backup catalog that you just copied to a copy that you can edit.
   
   This is the file that you need to update to preserve the timestamp, and that you will update to support any local user message changes.
   
```bash
dspcat -t -g /tmp/ftpdmsg.cat.backup >/tmp/ftpdmsg.cat.copy
```

3. Change the first line in the catalog from a comment to a z/OS UNIX `gencat` command, which enables the timestamp to be imbedded in the catalog when it is rebuilt.
   
```bash
cat /tmp/ftpdmsg.cat.copy
```

4. Update the catalog with your local modifications.

5. Rebuild the catalog with the `gencat` command.

   ```bash
gencat /tmp/ftpdmsg.cat.copy
```

6. Use the `gencat` command to update the shipped catalog with your modifications.

   ```bash
gencat /tmp/ftpdmsg.cat.copy /tmp/ftpdmsg.cat.backup
```

7. Verify that the timestamp is preserved.

   ```bash
date /tmp/ftpdmsg.cat
```

8. Replace the original catalog with the modified catalog.

   ```bash
mv /tmp/ftpdmsg.cat /tmp/ftpdmsg.cat.backup
mv /tmp/ftpdmsg.cat.copy /tmp/ftpdmsg.cat
```
a) Edit the file to be updated.

    oedit /tmp/ftpdmsg.cat.copy

b) Change the first line comment to add a `gencat` command to preserve the timestamp when the directory is built.

   The first line in the file will be similar to the following line:

   ```
   The time stamp of catalog /tmp/ftpdmsg.cat.backup is: 2006 095 20:30 UTC
   ```

   Replace the leading text on the line with the `gencat` subcommand `$timestamp` as follows:

   ```
   $timestamp 2006 095 20:30 UTC
   ```

   If this step is omitted and the original line is left in the catalog, when an attempt is made to generate a catalog from this file, you will see a message similar to the following message:

   ```
   FSUMS108 gencat: Invalid message number.
   ```

c) Save the file.

4. Update the catalog (/tmp/ftpdmsg.cat.copy) with any local modifications and save the file.

5. Build a new and customized catalog using the z/OS UNIX `gencat` command, and save a copy of the shipped level of the catalog.

    ```
    gencat /tmp/ftpdmsg.cat /tmp/ftpdmsg.cat.copy
    ```

   The correct response is:

   ```
   FSUMS105 gencat: Message catalog generated normally.
   ```

6. Browse the new catalog and verify that the timestamp from step “3” on page 657 matches what is in the file.

    ```
    obrowse /tmp/ftpdmsg.cat
    ```

   The first record contains the time stamp (**yyy yddd hh:mm UTC**). For example:

   ```
   ...2006 095 20:30 UTC
   ```

7. Replace the official z/OS UNIX catalog that is shipped with the release with the updated catalog that you created in step “5” on page 658.

**Results**

You know you are done when you test the catalogs to verify correct synchronization by performing the following actions:

1. Start the FTP server and inspect the syslog output (console if no syslog is running). Message EZYFS30W should not appear.

2. Using the FTP client, connect to the FTP server and inspect the SYSPRINT output. Message EZYFS31W should not appear.

   For more information about the `dspcat` and `gencat` utilities, see z/OS UNIX System Services Command Reference.

**Accounting**

The following parameters apply to SMF data:

- SMF
- SMFAPPE
configure the FTP server for SMF (optional)

The FTP server can write SMF type 118 (X'76') or type 119 (X'77') records to record transactions made by the FTP server. SMF records can be written for the following commands:

- APPE (append)
- DELE (delete)
- RNTO (rename)
- RETR (retrieve)
- STOR (store)
- STOU (store unique)

Information about the previous commands can be recorded for:

- FTP server running in normal data transfer mode (FILETYPE=SEQ)
- FTP server running remote job submission (FILETYPE=JES)
- FTP server running Structured Query Language (SQL) queries (FILETYPE=SQL)
- Any combination of SEQ, JES, and SQL

For commands involving data transfer (APPEND, RETR, STOU or STOR) an SMF record will be written for both successfully and unsuccessfully completed data transfer commands which have begun data transfer. For data transfer commands which have completed unsuccessfully, the byte count of transmission field will contain the number of bytes transferred before the failure, and the recent server reply field will contain the 3-digit error reply code sent to the client. See the information about type 118 records and type 119 records in z/OS Communications Server: IP Programmer’s Guide and Reference to find the particular offsets for the record type being used.

The FTP server can also write SMF records when a login attempt fails.

The capability also exists for a user-written exit routine to get control before the SMF records are written. See “Configuring the optional FTP user exits” on page 683 for more information.

If you want the FTP server to write SMF type 118 (X'76') or type 119 (X'77') SMF records, you must include at least one of the SMF subtype statements (SMF, SMFAPPE, SMFDEL, SMFLOGN, SMFREN, SMFRETR, or SMFSTOR) in the FTP.DATA data set.

If SMF subtype statements are not coded in the FTP.DATA data set, no SMF records are written by the FTP server.

For more information about enabling SMF TYPE 119 records for FTP Server, see SMF (FTP server) statement in z/OS Communications Server: IP Configuration Reference.

customizing transport layer security and Kerberos security

The following terms apply to Transport Layer Security (TLS) and Kerberos.
Integrity protected, data integrity, or data authentication
Indicates an algorithm is applied to the data being transferred, which modifies the data such that the receiving program can verify the data was not modified or changed during the transfer.

Privacy protected
Indicates an algorithm is applied to the data being transferred, which encrypts or scrambles the data such that only the receiving program can use a special key to decrypt or unscramble the data to its original format. The original data cannot be seen or interpreted while the data is in transit.

Raw
Indicates data is transmitted without being modified by any encryption or data integrity algorithms.

Encipher or cipher algorithm
Data being transferred is encrypted, integrity protected, or both. This term does not imply which algorithm is used and does not imply the data is encrypted.

Steps for customizing the FTP server for TLS
You can customize the FTP server for TLS, but a better way to implement TLS security is by using AT-TLS.

Before you begin
Understand the following information:

• The FTP server can be enabled to support both TLS and Kerberos. Some of the configuration statement settings apply to both TLS and Kerberos and affect the behavior of both.

• To support TLS, the FTP server always provides server certificate authentication to all the clients to validate that the server is what it says it is. Therefore, a server key ring database is required to contain at least the FTP server's digital certificate and private key. For more information about key ring databases, see Appendix B, “TLS/SSL security,” on page 1299.

• The FTP server can implement TLS security by itself, or the FTP server can be configured to use Application Transparent Transport Layer Security (AT-TLS) as a controlling application. For more information about AT-TLS, see Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1093.

Guideline: Using AT-TLS is the better way to implement TLS security. With AT-TLS, for example, you can have the following implementation:

– Specify the label of the certificate to be used for authentication instead of using the default certificate
– Support SSL Session Key Refresh
– Support SSL Sysplex Session ID Caching
– Trace decrypted SSL data for FTP in a data trace
– Receive more detailed diagnostic messages in syslogd

Requirement: AT-TLS requires Policy Agent to be configured, and the TCP/IP stack to be enabled for AT-TLS. To configure AT-TLS, see “Configuring the server system” on page 1098.

Procedure
Perform the following steps to customize the FTP server for TLS:

1. Decide what level of RFC 4217, On Securing FTP with TLS, that you want the server to support.

   • To have the server support On Securing FTP with TLS at the Internet draft level, code the following statement in the server's FTP.DATA configuration file:

     | TLSRFCLEVEL DRAFT

     This is the default. The z/OS FTP server has supported TLS security at this level since V1R2. Code this statement in FTP.DATA to maintain this level of support.
To have the server support *On Securing FTP with TLS* at the RFC 4217 level, code the following statement in the server’s FTP.DATA configuration file:

```
TLSRFCLEVEL RFC4217
```

The RFC *On Securing FTP with TLS* was published as RFC 4217 in October, 2005. The RFC differs from the Internet draft in its description of the AUTH, CCC, and REIN commands. RFC 4217 is less restrictive than the Internet draft regarding when the AUTH and CCC commands can be sent to the server, and more explicit about the details of the server REIN implementation. For more information, see RFC 4217.

2. Code the following statement in the server’s FTP.DATA configuration file to enable the server for TLS:

```
EXTENSIONS AUTH_TLS
```

3. Decide what level of authentication you will use for TLS sessions:

- Server authentication only
- Client authentication level 1
- Client authentication level 2
- Client authentication level 3

For more information about server authentication and client authentication, see “Secure Socket Layer overview” on page 1299.

4. Create the server key ring database and add the certificates you will need to the server key ring database.

Every TLS session handshake includes server authentication, so you must always add a certificate for this server to the server key ring database. If a server certificate is self signed, you must also export that certificate to the key ring databases of those clients that will log in using TLS. If a server certificate is signed by a certificate authority (CA), the CA certificate used to sign the server certificate needs to be in the client key ring databases, rather than the server certificate. For more information about server authentication, see “Server authentication ” on page 1299.

If you are using client authentication and self-signed certificates, you must import the client certificates into the server key ring database. If a client certificate is signed by a CA, the CA certificate used to sign the client certificate needs to be in the server key ring database, rather than the client certificate. For more information, see “Client authentication” on page 1300.

5. Decide whether FTP will implement TLS security or AT-TLS will implement TLS security.

The default is to have FTP implement TLS security. This setting is customized by using the TLSMECHANISM configuration statement.

- To configure the FTP server to use AT-TLS for TLS security, code the following statement in FTP.DATA:

```
TLSMECHANISM ATTLS
```

- To configure the FTP server to implement TLS security by itself, code the following statement in FTP.DATA:

```
TLSMECHANISM FTP
```

This is the default setting.

6. If using TLSMECHANISM FTP, you must configure the FTP server with a key ring database.

To configure the FTP server with the name of the key ring database, code the following statement in FTP.DATA:

```
KEYRING server-keyring-database
```

For information about the KEYRING statement, see *z/OS Communications Server: IP Configuration Reference*. 

Transferring files using FTP 661
7. Decide whether clients logging in to this server should be required to use the TLS protocol. The default is to allow the client to decide whether to use TLS. This setting is customized by using the SECURE_FTP configuration statement. You should understand that its setting affects both TLS security behavior and Kerberos security behavior.

To allow the client to decide whether to use TLS, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_FTP ALLOWED
```

This is the default setting, and indicates:

- If the server is enabled for TLS only, clients must either log in using TLS, or with no security mechanism.
- If the server is enabled for Kerberos only, clients must either log in using Kerberos, or with no security mechanism.
- If the server is enabled for both TLS and Kerberos, clients can log in using TLS, Kerberos, or with no security mechanism.

To require that clients log in using a security mechanism, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_FTP REQUIRED
```

This setting indicates:

- If the server is enabled for TLS only, clients must log in using TLS.
- If the server is enabled for Kerberos only, clients must log in using Kerberos.
- If the server is enabled for both TLS and Kerberos, clients must log in using either TLS or Kerberos.

8. If you do not want to use client authentication, you can code the following statement in the server's FTP.DATA configuration file:

```
SECURE_LOGIN NO_CLIENT_AUTH
```

This is the default.

If you do want to use client authentication, the following levels of client authentication are possible:

- **Level 1 authentication** is performed by system SSL. The client passes an X.509 certificate to the server. To pass authentication, the Certificate Authority that signed the client certificate must be considered trusted by the server. To use level 1 client authentication, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_LOGIN REQUIRED
```

- **Level 2 authentication** provides level 1 authentication, and additionally requires that the client certificate be registered with RACF (or another SAF compliant security product) and mapped to a user ID. The client certificate received during the SSL handshake is used to query the security product to verify that the certificate maps to a user ID known to the system prior to connection negotiation. To use level 2 client authentication, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_LOGIN VERIFY_USER
```

- **Level 3 authentication** provides level 1 and 2 authentication. In addition, it provides the capability to restrict access to the server based on the user ID returned from RACF. If the SERVAUTH class of RACF is active and the server's port profile is defined, a connection is accepted only if the requester's user ID associated with the client certificate is defined in the server's port profile. To
use level 3 client authentication, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_LOGIN VERIFY_USER
```

Also, define the server's port profile in the SERVAUTH class of RACF.

If you choose to use client authentication, you can also use the client certificate authentication process to eliminate the client login password prompt so that a client supplies only the login user ID to establish the session. The certificate received from the client must be registered in the security product and must be associated with the login user ID. You can use the RACDCERT ADD command to register and associate the certificate. If either the certificate is not registered or is not associated with the user ID, you will be prompted for a password.

If you do not want to use the client authentication process to eliminate the client password prompt, you can code the following statement in the server's FTP.DATA configuration file:

```
SECURE_PASSWORD REQUIRED
```

This is the default.

If you want to use the client authentication process to eliminate the client password prompt, along with your client authentication statement (either SECURE_LOGIN REQUIRED or SECURE_LOGIN VERIFY_USER), code the following statement in the server's FTP.DATA configuration file:

```
SECURE_PASSWORD OPTIONAL
```

9. If you specified TLSMECHANISM ATTLS, configure the AT-TLS policy for the FTP server.

To configure AT-TLS, see “Configuring the server system” on page 1098.

Requirements:

- The FTP server is a controlling application. For more information about controlling applications, see “Advanced application considerations” on page 1114.

  Code a TTLSEnvironmentAdvancedParms statement with the ApplicationControlled and SecondaryMap parameters; both parameters should specify the value On. The ApplicationControlled parameter allows FTP to start and stop TLS security on a connection. The SecondaryMap parameter enables active or passive data connections to use the AT-TLS policy that is used for the control connection. You do not need to code any additional TTLSRule statements for the data connections.

- The FTP server requires that the HandshakeRole parameter with the value Server or ServerWithClientAuth be coded on the TTLSEnvironmentAction statement. If the SECURE_LOGIN statement is coded in FTP.DATA with the parameters REQUIRED or VERIFY_USER, the HandshakeRole parameter value must be ServerWithClientAuth.

- The TTLSRule statement for the FTP server requires the Direction parameter with the value Inbound.

A sample Policy Agent AT-TLS configuration showing the required policy configuration statements for AT-TLS is as follows:

```
TTLSEnvironmentAction secure_ftp_server_env
{
    TTLSKeyringParms
    {
        Keyring server-keyring-database
    }
    HandshakeRole Server  # When Secure_Login NO_CLIENT_AUTH is coded
    #HandshakeRole ServerWithClientAuth  # When Secure_Login Required or Verify_User is coded
    TTLSEnvironmentAdvancedParms
    {
        ApplicationControlled On
        SecondaryMap On
    }
}
```
TTLSCipherParmsRef ftp_server_ciphers # Used to customize ciphersuites for the FTP server

TTLSCipherParms ftp_server_ciphers
{
    # Sample ciphers. Should be customized!
    V3CipherSuites TLS_RSA_WITH_AES_256_CBC_SHA
    V3CipherSuites TLS_RSA_WITH_3DES_EDE_CBC_SHA
    V3CipherSuites TLS_RSA_WITH_NULL_SHA
}

TTLSRule secure_ftp_server_rule
{
    LocalPortRange 21                   # This should be set to the port the FTP server is listening on
    Direction Inbound
    TTLSGroupActionRef secure_ftp_server_group
    TTLSEnvironmentActionRef secure_ftp_server_env
}

Tip: You can enable additional security settings with AT-TLS, such as LDAP servers and handshake timeout values. The configuration used in the example is the minimum required to allow the FTP server to use AT-TLS. You can add additional configuration statements.

10. Decide which cipher algorithms the server should use to encipher data transfers and to encipher control information.

FTP and AT-TLS support TLS through the system SSL cryptographic services base element of z/OS. System SSL supports multiple cipher algorithms that provide both encryption and data authentication (that is, data integrity). Encryption scrambles the data so it is transferred confidentially and cannot be interpreted without a special key. Data authentication algorithms ensure the data was not modified during transfer. Some of the supplied cipher algorithms provide only data authentication, and some provide both encryption and authentication. Be aware that the actual cipher algorithm used for the session is determined by a negotiation between the server and client. For example, if you configure an FTP server to use the Triple DES encryption, SHA authentication algorithm, but the client does not support that cipher algorithm, Triple DES encryption, SHA authentication will not be used for sessions between the server and that client.

If using TLSMECHANISM FTP, select which cipher algorithms you prefer to use by coding a CIPHERSUITE configuration statement in the FTP.DATA file for each cipher algorithm the server can use. For a list of the cipher algorithms you can specify on the CIPHERSUITE statement, see z/OS Communications Server: IP Configuration Reference. List the CIPHERSUITE statements in FTP.DATA in the order of preference, your most preferred cipher algorithm being first. System SSL will negotiate a cipher algorithm with the server on behalf of the client using the same order of preference as is indicated by the order of CIPHERSUITE statements in FTP.DATA.

If you specify TLSMECHANISM AT-TLS, select which cipher algorithms you want to use by coding a TTLSCipherParms configuration statement to specify the cipher algorithms that the server can use. For a list of the cipher algorithms you can specify with the TTLSCipherParms statement, see z/OS Communications Server: IP Configuration Reference. List the ciphers in the order of preference, your most preferred cipher algorithm first. The cipher algorithm is negotiated with the server on behalf of the client using the same order of preference as indicated by the order of the TTLSCipherParms statement.

Restrictions:
- Only RSA key exchange is supported.
- The following algorithms are subject to export regulations and might not be available to your system:
  - Triple DES encryption, SHA authentication
  - RC4 (128-bit) encryption, SHA authentication
  - RC4 (128-bit) encryption, MD5 authentication
  - AES (128-bit and 256-bit) encryption, SHA authentication

Guideline: The default ciphers used by System SSL support a null cipher, which has no encryption or authentication. A TTLSCipherParms statement or CIPHERSUITE statement should be coded to remove the null cipher from the list of acceptable ciphers.
11. Decide the level of security for the data connection.

You can choose to require enciphered data transfers, or to allow the client to decide the level of security for data transfers. The default is to allow the clients to decide the level of security.

This setting is customized by using the SECURE_DATACONN configuration statement. You should understand that its setting affects both TLS security behavior and Kerberos security behavior.

If you want the server to require that data is transferred raw with no cipher algorithm applied to the data and that clients attempting to use ciphers are rejected, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_DATACONN NEVER
```

If you want the client to decide whether data is transferred raw or enciphered, you can code the following statement in the server's FTP.DATA configuration file:

```
SECURE_DATACONN CLEAR
```

This is the default.

For TLS, the client decides whether data is enciphered or not. If it indicates it should be enciphered, the cipher algorithm is negotiated between the server and the client using TLS protocols. For Kerberos, the client can specify whether data is transferred raw, integrity protected only, or both integrity and privacy protected.

If you want the server to require that data is transferred enciphered and that clients attempting to send raw data are rejected, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_DATACONN PRIVATE
```

For TLS, the cipher algorithm is negotiated between the server and the client using TLS protocols. For Kerberos, the data must be transferred using both integrity and privacy protection. Clients attempting to send data that is only integrity protected are rejected.

12. Decide whether the server requires session reuse when SSL/TLS is used to protect the control and data connections.

By default, the server is enabled to reuse either of the following SSL session IDs on the data connections within an FTP session:

- The SSL session ID of the control connection
- The SSL session ID of a previous data connection

This setting is customized by using the SECURE_SESSION_REUSE configuration statement.

- To enable the server to reuse either of the following SSL session IDs on the subsequent data connections within an FTP session, code ALLOWED on the SECURE_SESSION_REUSE statement in the FTP.DATA configuration file of the server:
  - The SSL session ID of the control connection
  - The SSL session ID of a previous data connection

  This is the default.

- To require the server to reuse the SSL session ID of the control connection on the subsequent data connections within an FTP session, code REQUIRED on the SECURE_SESSION_REUSE statement in the FTP.DATA configuration file of the server.

  This setting might cause data connections and FTP transfers to fail when the remote side does not support reusing the session ID.

For information about the SECURE_SESSION_REUSE statement, see z/OS Communications Server: IP Configuration Reference.

13. For information about configuring your security product for TLS, see Appendix B, “TLS/SSL security,” on page 1299.
Steps for customizing the FTP server for Kerberos

The FTP server can be enabled to support both TLS and Kerberos.

Before you begin
Some configuration statement settings apply to both TLS and Kerberos and affect the behavior of both.

Decide which RACF ID the service principal is to be associated with, which helps determine whether a keytab file is required. If the service principal is associated with the FTP startup procedure ID, a keytab file is not required. If a keytab file is not required and you do not plan to use one, decide how the FTP startup procedure is to be updated to identify the environment variable (ENVAR) KRBS_SERVER_KEYTAB.

Procedure
Perform the following steps to customize the FTP server for Kerberos:

1. Code the following statement in the server's FTP.DATA configuration file to enable the server for Kerberos:

   ```
   EXTENSIONS AUTH_GSSAPI
   ```

2. Decide whether clients should be required to use the Kerberos protocol.

   The default is to allow the client to decide whether to use Kerberos.

   This setting is customized using the SECURE_FTP configuration statement. You should understand that its setting affects both TLS security behavior and Kerberos security behavior.

   To allow the client to decide whether to use Kerberos, you can code the following statement in the server's FTP.DATA configuration file:

   ```
   SECURE_FTP ALLOWED
   ```

   This is the default setting, and indicates:

   • If the server is enabled for TLS only, clients must either log in using TLS, or with no security mechanism.
   • If the server is enabled for Kerberos only, clients must either log in using Kerberos, or with no security mechanism.
   • If the server is enabled for both TLS and Kerberos, clients can log in using TLS, Kerberos, or with no security mechanism.

   To require that clients log in using Kerberos, code the following statement in the server's FTP.DATA configuration file:

   ```
   SECURE_FTP REQUIRED
   ```

   This setting indicates:

   • If the server is enabled for TLS only, clients must log in using TLS.
   • If the server is enabled for Kerberos only, clients must log in using Kerberos.
   • If the server is enabled for both TLS and Kerberos, clients must log in using either TLS or Kerberos.

3. Decide whether to use the client authentication process to eliminate the client login password prompt so that a client supplies only the login user ID to establish the session.

   The Kerberos principal that is received from the client is used to query the security product (either RACF or another SAF-compliant security product) to determine whether the Kerberos principal maps to a user ID that is known to the system. If the Kerberos principal maps to a user ID, and that user ID matches the user name passed from the client on the USER command, you can eliminate the password prompt.

   If the client principal is for the same realm as the FTP server, the principal is correlated to the user ID using the KERBNAME option of the ADDUSER or ALTUSER commands. If the client principal is a cross-realm principal, it is correlated to the user ID using the RDEFINE KERBLINK command.
If you want to require the client to provide a password or password phrase even when the client authentication process does not require it, code the following statement in the server’s FTP.DATA configuration file. This is the default.

SECURE_PASSWORD_KERBEROS REQUIRED

If you want to use the client authentication process to eliminate the client password prompt, code the following statement in the server’s FTP.DATA configuration file:

SECURE_PASSWORD_KERBEROS OPTIONAL

4. Decide the level of security for the data connection.

You can choose to require enciphered data transfers, or to allow the client to decide the level of security for data transfers. The default is to allow the clients to decide the level of security.

This setting is customized using the SECURE_DATACONN configuration statement. You should understand that its setting affects both TLS security behavior and Kerberos security behavior.

If you want the server to require that data is transferred raw with no cipher algorithm applied to the data and that clients attempting to use ciphers are rejected, code the following statement in the server’s FTP.DATA configuration file:

SECURE_DATACONN NEVER

If you want the client to decide whether data is transferred raw or enciphered, you can code the following statement in the server’s FTP.DATA configuration file:

SECURE_DATACONN CLEAR

This is the default.

For TLS, the client decides whether data is enciphered or not. If it indicates it should be enciphered, the cipher algorithm is negotiated between the server and the client using TLS protocols. For Kerberos, the client can specify whether data is transferred raw, integrity protected only, or both integrity and privacy protected.

If you want the server to require that data is transferred both integrity and privacy protected, code the following statement in the server’s FTP.DATA configuration file:

SECURE_DATACONN PRIVATE

For TLS, the cipher algorithm is negotiated between the server and the client using TLS protocols, and clients attempting to send raw data are rejected. For Kerberos, the data must be transferred using both integrity and privacy protection, and clients attempting to send raw data or data that is only integrity protected are rejected.

If you want the server to require that data is transferred integrity protected only or both integrity and privacy protected, code the following statement in the server’s FTP.DATA configuration file:

SECURE_DATACONN SAFE

For TLS, specifying this option is identical to specifying SECURE_DATACONN PRIVATE. For Kerberos, specifying this option indicates the data can be transferred integrity protected only, or both integrity and privacy protected. Clients attempting to send raw data are rejected.

5. Ensure that the RACF user ID under which the FTP client will execute has permission to the ICSF callable services that Kerberos needs. Specifically, if the CSFSERV class is active, ensure that the user ID has read access to the following ICSF SAF resources:

CSF1TRC, CSF1SKE, CSF1SKD, CSF1TRD, and CSFOWH

6. Decide the level of security for the control connection (that is, for FTP commands and replies).

You can choose to require enciphered control connection data, or to allow the client to decide the level of security. The default is to allow the clients to decide the level of security.
This setting is customized using the SECURE_CTRLCONN configuration statement. This setting applies only to Kerberos. For TLS, the control connection is required to be enciphered and this setting has no effect on TLS behavior.

If you want the client to decide whether control data is transferred raw or enciphered, you can code the following statement in the server’s FTP.DATA configuration file:

```
SECURE_CTRLCONN CLEAR
```

This is the default.

The client can specify whether data is transferred raw, integrity protected only, or both integrity and privacy protected.

If you want the server to require that control data is transferred both integrity and privacy protected, code the following statement in the server’s FTP.DATA configuration file:

```
SECURE_CTRLCONN PRIVATE
```

Clients attempting to send raw data or data that is only integrity protected are rejected.

If you want the server to require that data is transferred integrity protected only or both integrity and privacy protected, code the following statement in the server’s FTP.DATA configuration file:

```
SECURE_CTRLCONN SAFE
```

Clients attempting to send raw data are rejected.

7. Create the service principal against a RACF ID for use with a keytab (see step 7 for using Kerberos with no keytab).

a) Create a RACF user ID to associate with the FTP service principal.

```
adduser FTP NOPASSWORD DFLTGRP(SYS1) omvs(autouid home('/u/ftp') prog('/bin/sh'))
```

b) After the FTP RACF user ID is created, add the Kerberos principal to it.

```
ALTUSER FTP KERB(KERBNAME(ftp/<hostname>))
```

c) To ensure the Kerberos segment was added, use the following command to display the ID.

```
LU FTP NORACF KERB
```

**Result:**

```
USER=FTP
KERB INFORMATION
--------------------
KERBNAME= ftp/<hostname>
KEY VERSION= 001
KEY ENCRYPTION TYPE= DES DES3 DESD
```

d) To add the FTP service principal to the keytab file, take the following actions:

1) The keytab file is located in the /etc/skrb directory. Switch to that directory using the following command:

```
cd /etc/skrb
```

2) Use the following command to see what is currently in the keytab file:

```
keytab list
```
If nothing is currently in the keytab file, the following information is returned:

```
Key table: /etc/skrb/krb5.keytab
```

3) Add the FTP service principle using the following command:

```
keytab add ftp/<hostname>
```

You will be prompted for the principals’ password. For this example, that password is FTP. The password must be entered in uppercase. This password was assigned with the RACF ALTUSER command when the FTP service principal was created.

4) Issue the keytab list command again.

The following information is displayed when the FTP service principal is present:

```
Key table: /etc/skrb/krb5.keytab
Principal: ftp/<hostname>@<realm>
  Key version: 1
  Key type: 56-bit DES
  Entry timestamp: 2005/02/04-16:21:10
Principal: ftp/<hostname>@<realm>
  Key version: 1
  Key type: 56-bit DES using key derivation
  Entry timestamp: 2005/02/04-16:21:10
Principal: ftp/<hostname>@<realm>
  Key version: 1
  Key type: 168-bit DES using key derivation
  Entry timestamp: 2005/02/04-16:21:10
```

8. An alternate way to run without a keytab file is to associate the FTP service principal to the ID under which the FTP started task runs.

If the ID that the FTP started task runs under is FTPD, issue the following command to create the FTP service principal and have it associated to that ID.

```
ALTUSER FTPD PASSWORD(ftpd) NOEXPIRED KERB(KERBNAME(ftp/<hostname>))
```

**Rule:** In this setup, you must set the KRBS5_SERVER_KEYTAB environment variable. Specify it directly in the FTP startup procedure as follows:

```
//FTPD   EXEC PGM=&MODULE,REGION=4096K,TIME=NOLIMIT,
//      PARM=('POSIX(ON) ALL31(ON)',
//        'ENVAR("KRB5_SERVER_KEYTAB=1")/&PARMS')
```

Another way of specifying the environment variable directly in the startup procedure is to specify a file where the environment variables are listed.

```
//FTPD   EXEC PGM=&MODULE,REGION=4096K,TIME=NOLIMIT,
//      PARM=('POSIX(ON) ALL31(ON)',
//        'ENVAR("_CEE_ENVFILE=/etc/ftp.envvars")/&PARMS')
```

Then, within the /etc/ftp.envvars file, add the following entry:

```
KRBS5_SERVER_KEYTAB=1
```

9. Ensure that the FTP RACF user ID has permission to the ICSF callable services that Kerberos needs. Specifically, if the CSFSERV class is active, ensure that the user ID has read access to the following ICSF SAF resources:

CSF1TRC, CSF1SKE, CSF1SKD, CSF1TRD, and CSFOWH

**Results**

You know you are done when a client is able to successfully log in to the FTP server using Kerberos. An example of the login is as follows:
1. Obtain the Kerberos credentials by issuing the following command:

   ```bash
   kinit joe
   ```

2. You will be prompted for the password. Enter it.

3. Issue the `ftp` command:

   ```bash
   ftp <hostname>
   ```

You should see the following information:

```plaintext
Using /u/JOE/ftp.data for local site configuration parameters.
IBM FTP CS V1R9
FTP: using TCPIP
Connecting to: <hostname><ip address> port: <port number>.
220 Connection will close if idle for more than 5 minutes.
>>> AUTH GSSAPI
334 Using authentication mechanism GSSAPI
>>> ADAT
235 ADAT=Y6gGCSqgSi3b3eECAg1Ab1kwV6ADAgEFoQMCAQ+iSzBjoAMC7moS==
Authentication negotiation succeeded
NAME (<hostname>):USER:
JOE
>>> USER JOE
331 Send password please.
PASSWORD:
>>> PASS
230 JOE is logged on. Working directory is "JOE".
Command:
```

**Tip:** The password prompt is skipped if the server is configured with SECURE_PASSWORD_KERBEROS OPTIONAL and the client’s Kerberos ticket principal name matches the logon user ID.

### Steps for customizing the FTP client for TLS

You can customize the FTP client for TLS, but a better way to implement TLS security is by using AT-TLS.

**Before you begin**

Understand the following information:

- The FTP client can be enabled to use either TLS or Kerberos, but not both at the same time.

- To support TLS, the FTP server always provides server certificate authentication to all the clients to validate that the server is what it says it is. Therefore, a client key ring database is required to contain at least the certificate for the CA that signed the server certificate (or the server certificate if the server certificate is self-signed). For more information about key ring databases, see Appendix B, “TLS/SSL security,” on page 1299.

- The FTP client can implement TLS security by itself, or the FTP client can be configured to use Application Transparent Transport Layer Security (AT-TLS) as a controlling application. For more information on AT-TLS, see Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1093.

**Guideline:** Using AT-TLS is the best way to implement TLS security. With AT-TLS, for example, you can have the following implementation:

- Specify the label of the certificate to be used for authentication instead of using the default certificate
- Support SSL Session Key Refresh
- Support SSL Sysplex Session ID Caching
- Trace decrypted SSL data for FTP in a data trace
- Receive more detailed diagnostic messages in syslogd

**Requirement:** AT-TLS requires Policy Agent to be configured, and the TCP/IP stack to be enabled for AT-TLS. To configure AT-TLS, see “Configuring the client systems” on page 1100.
Procedure

Perform the following steps to customize the FTP client for TLS:

1. Decide what level of RFC 4217, *On Securing FTP with TLS*, that you want the client to support.
   
   - To have the client support *On Securing FTP with TLS* at the Internet draft level, code the following statement in the client's FTP.DATA configuration file:
     
     ```
     TLSRFCLEVEL DRAFT
     ```
     
     This is the default. The z/OS FTP client has supported TLS security at this level since V1R2. Code this statement in FTP.DATA to maintain this level of support.
   
   - To have the client support *On Securing FTP with TLS* at the RFC 4217 level, code the following statement in the client's FTP.DATA configuration file:
     
     ```
     TLSRFCLEVEL RFC4217
     ```
     
     The RFC *On Securing FTP with TLS* was published as RFC 4217 in October, 2005. The RFC differs from the Internet draft in its description of the AUTH, CCC, and REIN commands. This has implications for client subcommands such as AUTH and CCC. Generally, RFC 4217 is less restrictive than the Internet draft. For more information, see RFC 4217. For more information on RFC 4217 and using security mechanisms, see z/OS Communications Server: IP User's Guide and Commands.

2. Code the following statement in the client's FTP.DATA configuration file to enable the client for TLS:
   
   ```
   SECURE_MECHANISM TLS
   ```

3. Decide what level of authentication you will use for TLS sessions:
   
   - Server authentication only
   - Client authentication level 1
   - Client authentication level 2
   - Client authentication level 3

   For more information about server authentication and client authentication, see “Secure Socket Layer overview” on page 1299.

4. Use a CERTAUTH virtual key ring, or create a client key ring database and add the certificates that you need to that database.

   If you are using server authentication only and the FTP server certificate is signed by a certificate authority (CA), the FTP client can use a CERTAUTH virtual key ring and you do not need to create a client key ring database. To use a CERTAUTH virtual key ring, use the key ring name *AUTH*/*/.

   If you cannot use a virtual key ring, create the client key ring database and add the certificates that you need to that database.

   Every TLS session handshake includes server authentication. If a server certificate is self-signed, you must import that certificate to the key ring database of any client that will log in using TLS. If the server certificate is signed by a CA, the CA certificate used to sign the server certificate (rather than the server certificate itself) needs to be in the client key ring database. For more information, see “Server authentication ” on page 1299.

   If you are using client authentication, you must add a certificate for the client to the client key ring database.

   If you are using client authentication and self-signed client certificates, you must add a certificate for the client to the server key ring database. If a client certificate is signed by a CA, the CA certificate used to sign the client certificate needs to be in the server key ring database, rather than the client certificate.

   For information about the client certificates you must create, see “Client authentication” on page 1300.

5. Decide whether FTP will implement TLS security or AT-TLS will implement TLS security.
The default is to have FTP implement TLS security. This setting is customized using the
TLSMECHANISM configuration statement.

- To configure the FTP client to use AT-TLS for TLS security, code the following statement in
FTP.DATA:

```
TLSMECHANISM ATTLS
```

- To configure the FTP client to implement TLS security by itself, code the following statement in
FTP.DATA:

```
TLSMECHANISM FTP
```

This is the default setting.

6. If using TLSMECHANISM FTP, you must configure the FTP client with the name of the key ring
database.

Code the following statement in FTP.DATA:

```
KEYRING client-keyring-database
```

For information about the KEYRING statement, see z/OS Communications Server: IP Configuration
Reference.

7. If you specified TLSMECHANISM ATTLS, configure the AT-TLS policy for the FTP client.

To configure AT-TLS, see “Configuring the client systems” on page 1100.

Requirements:

- The FTP server and client are controlling applications. For more information about controlling
applications, see “Advanced application considerations” on page 1114.

Code a TTLSEnvironmentAdvancedParms statement with the ApplicationControlled and
SecondaryMap parameters; both parameters should specify the value On. The
ApplicationControlled parameter allows FTP to start and stop TLS security on a connection. The
SecondaryMap parameter enables active or passive data connections to use the AT-TLS policy that
is used for the control connection. You do not need to code any additional TTLSRule statements for
the data connections.

- The FTP client requires the HandshakeRole parameter with the value Client to be coded on the
TTLSEnvironmentAction statement.

- The TTLSRule statement for the FTP client requires the Direction parameter with the value
Outbound.

A sample Policy Agent AT-TLS configuration showing the required policy configuration statements for
AT-TLS is as follows:

```
TTLSGroupAction  secure_ftp_client_group
{
  TTSEnabled  On
}
TTLSEnvironmentAction  secure_ftp_client_env
{
  TTLSKeyringParms
  {
    Keyring  client-keyring-database
  }
  HandshakeRole  Client
  TTLSEnvironmentAdvancedParms
  {
    ApplicationControlled  On
    SecondaryMap  On
  }
  TTLSCipherParmsRef  ftp_client_ciphers  # Used to customize ciphersuites
}
TTLSCipherParms  ftp_client_ciphers
```
Tip: You can enable additional security settings with AT-TLS, such as LDAP servers and handshake timeout values. The sample configuration is only the minimum required to allow the FTP client to use AT-TLS. You can add additional configuration statements.

8. Decide which cipher algorithms the client should use to encipher data transfers and control information.

FTP and AT-TLS support TLS through the system SSL cryptographic services base element of z/OS. System SSL supports multiple cipher algorithms that provide both encryption and data authentication (that is, data integrity). Encryption scrambles the data so it is transferred confidentially and cannot be interpreted without a special key. Data authentication algorithms ensure that the data was not modified during transfer. Some of the supplied cipher algorithms provide only data authentication, and some provide both encryption and authentication. Be aware that the actual cipher algorithm used for the session is determined by a negotiation between the server and client. For example, if you configure an FTP client to use the Triple DES encryption, SHA authentication algorithm, but the server does not support that cipher algorithm, Triple DES encryption, SHA authentication will not be used for sessions between the client and that server.

If using TLSMECHANISM FTP, select which cipher algorithms you prefer to use by coding a CIPHERSUITE configuration statement in the FTP.DATA file for each cipher algorithm the client can use. For a list of the cipher algorithms you can specify on the CIPHERSUITE statement, see z/OS Communications Server: IP Configuration Reference.

If you specify TLSMECHANISM ATTLS, select which cipher algorithms you want to use by coding a TTLSCipherParms configuration statement to specify the cipher algorithms the client can use. For a list of the cipher algorithms you can specify with the TTLSCipherParms statement, see z/OS Communications Server: IP Configuration Reference. List the ciphers in the order of preference, your most preferred cipher algorithm first. The cipher algorithm is negotiated with the server on behalf of the client using the same order of preference as is indicated by the order of the TTLSCipherParms statement.

Restrictions:

- Only RSA key exchange is supported.
- The following algorithms are subject to export regulations and might not be available to your system:
  - Triple DES encryption, SHA authentication
  - RC4 (128-bit) encryption, SHA authentication
  - RC4 (128-bit) encryption, MD5 authentication
  - AES (128-bit and 256-bit) encryption, SHA authentication

Guideline: The default ciphers used by System SSL support a null cipher, which has no encryption or authentication. A TTLSCipherParms statement or CIPHERSUITE statement should be coded to remove the null cipher from the list of acceptable ciphers.

9. Decide whether the client should be required to use the TLS protocol.

If the FTP server does not support TLS, you can choose to allow the client to log in without using the TLS security, or require the client to use a secure session, thus failing the login. The default is to not...
require the client to use TLS. This setting is customized using the SECURE_FTP configuration statement.

To have the client log in using the TLS protocol when the server supports TLS, and log in without TLS when the server does not support TLS, code the following statement in the client's FTP.DATA configuration file:

```plaintext
SECURE_FTP ALLOWED
```

This is the default.

To have the client log in using the TLS protocol, but close the server connection and prevent logging in when the server does not support TLS, code the following statement in the client's FTP.DATA configuration file:

```plaintext
SECURE_FTP REQUIRED
```

10. Decide the level of security for the data connection.

You can choose to require enciphered data transfers, or to allow the FTP user to decide the level of security for data transfers. The default is to not encipher the data, but allow the data to be enciphered at the server's request or by the FTP user's request during the FTP session.

Note that the level of security for data connections is determined by both the SECURE_DATACONN statement in FTP.DATA and by subcommands an FTP user might issue during an FTP session.

The following subcommands can be issued by the user:

- **clear**
  
  Resets the security level so that data is transferred raw.

- **private**
  
  Resets the security level so that data is transferred enciphered. The cipher algorithm is negotiated between the server and the client using the TLS protocol negotiation.

If you want the client to transfer data raw with no cipher algorithm applied to the data, code the following statement in the client's FTP.DATA configuration file:

```plaintext
SECURE_DATACONN NEVER
```

To indicate the data can be transferred raw or enciphered, code the following statement in the client's FTP.DATA configuration file:

```plaintext
SECURE_DATACONN CLEAR
```

This is the default.

By default, data is transferred raw. However, the user can issue the `private` subcommand during the FTP session to change the data connection security level, so that data is transferred enciphered. The user can also issue the `clear` subcommand to reset the data connection security level back, so that data is transferred raw again. For TLS, if the `private` subcommand is issued, the cipher algorithm is negotiated between the server and the client using TLS protocols.

If you want to require that data is transferred enciphered, code the following statement in the client's FTP.DATA configuration file:

```plaintext
SECURE_DATACONN PRIVATE
```

For TLS, the cipher algorithm is negotiated between the server and the client using TLS protocols.

11. Decide whether the client requires session reuse when SSL/TLS is used to protect the control and data connections.

By default, the setting is not enabled for the client to reuse either of the following SSL session IDs on subsequent data connections within an FTP session:

- The SSL session ID of the control connection
• The SSL session ID of a previous data connection
This setting is customized by using the SECURE_SESSION_REUSE configuration statement.
• If you do not require the client to reuse either of the following SSL session IDs on subsequent data connections within an FTP session, code NONE on the SECURE_SESSION_REUSE statement in the FTP.DATA configuration file of the client:
  – The SSL session ID of the control connection
  – The SSL session ID of a previous data connection
This is the default.
• To enable the client to reuse either of the following SSL session IDs on subsequent data connections within an FTP session, code ALLOWED on the SECURE_SESSION_REUSE statement in the FTP.DATA configuration file of the client:
  – The SSL session ID of the control connection
  – The SSL session ID of a previous data connection
• To require the client to reuse the SSL session ID of the control connection on the subsequent data connections within an FTP session, code the SECURE_SESSION_REUSE REQUIRED statement in the FTP.DATA configuration file of the client.
  This setting might cause data connections and FTP transfers to fail when the remote side does not support reusing the session ID.
For information about the SECURE_SESSION_REUSE statement, see z/OS Communications Server: IP Configuration Reference.

Steps for customizing the FTP client for Kerberos

The FTP client can be enabled to use either TLS or Kerberos, but not both at the same time.

Procedure

Perform the following steps to customize the FTP client for Kerberos:

1. Code the following statement in the client's FTP.DATA configuration file to enable the client for Kerberos:

   ```plaintext
   SECURE_MECHANISM GSSAPI
   ```

2. Decide whether the client should be required to use the Kerberos protocol.
   If the FTP server does not support Kerberos, you can choose to allow the client to log in without using Kerberos security, or require the client to use a secure session, thus failing the login. The default is to not require the client to use Kerberos. This setting is customized using the SECURE_FTP configuration statement.

   To have the client log in using the Kerberos protocol, but if the server does not support Kerberos allow the client to complete the login without using it, code the following statement in the client's FTP.DATA configuration file:

   ```plaintext
   SECURE_FTP ALLOWED
   ```
   This is the default.

   To have the client log in using the Kerberos protocol, but if the server does not support Kerberos have the login fail and not allow the client to log in, code the following statement in the client's FTP.DATA configuration file:

   ```plaintext
   SECURE_FTP REQUIRED
   ```

3. Decide the level of security for the data connection.
You can choose to require enciphered data transfers, or to allow the FTP user to decide the level of security for data transfers. The default is to not encipher the data, but allow the data to be enciphered at the server's request or at the FTP user's request during the FTP session.

Note that the level of security for data connections is determined by both the SECURE_DATACONN statement in FTP.DATA and by subcommands an FTP user might issue during an FTP session.

The following subcommands can be issued by the user:

**clear**
- Resets the security level so that data is transferred raw.

**private**
- Resets the security level so that data is transferred enciphered. If the client is using the Kerberos security mechanism, the data is transferred both integrity protected and privacy protected. If the client is using the TLS security mechanism, the cipher algorithm is negotiated between the server and the client using the TLS protocol negotiation.

**safe**
- Resets the security level so that data is transferred integrity protected only.

If you want the client to transfer data raw with no cipher algorithm applied to the data, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_DATACONN NEVER
```

To indicate the data can be transferred raw or enciphered, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_DATACONN CLEAR
```

This is the default.

By default, data is transferred raw. However, the user can issue the `private` subcommand during the FTP session to change the data connection security level, so that data is transferred both integrity and privacy protected. The user can also issue the `safe` subcommand to change the data connection security level so that data is transferred integrity protected only, or the `clear` subcommand to reset the data connection security level back so that data is transferred raw again.

If you want to require that data is transferred both integrity and privacy protected, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_DATACONN PRIVATE
```

If you want to require that data is transferred integrity protected only, or both integrity and privacy protected, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_DATACONN SAFE
```

By default, data is transferred integrity protected only. However, the user can issue the `private` subcommand during the FTP session to change the data connection security level so that data is transferred both integrity and privacy protected. The user can also issue the `safe` subcommand to reset the data connection security level back, so that data is transferred integrity protected only.

4. Decide the level of security for the control connection (that is, for FTP commands and replies).

You can choose to require enciphered data, or to allow the FTP user to decide the level of security. The default is to not encipher the data, but allow the data to be enciphered at the server's request or at the FTP user's request during the FTP session.

Note that the level of security for data connections is determined by both the SECURE_CTRLCONN statement in FTP.DATA and by subcommands an FTP user might issue during an FTP session.

The following subcommands can be issued by the user:
cprotect clear
   Resets the security level so that data is transferred raw.

cprotect private
   Resets the security level so that data is transferred both integrity protected and privacy protected.

cprotect safe
   Resets the security level so that data is transferred integrity protected only.

To indicate the data can be transferred raw or enciphered, you can code the following statement in the server's FTP.DATA configuration file:

   SECURE_CTRLCONN CLEAR

This is the default.

By default, data is transferred raw. However, the user can issue the cprotect private subcommand during the FTP session to change the security level so that data is transferred both integrity and privacy protected. The user can also issue the cprotect safe subcommand to change the security level so that data is transferred integrity protected only, and the cprotect clear subcommand to reset the security level back so that data is transferred raw again.

If you want to require that data is transferred both integrity and privacy protected, code the following statement in the client's FTP.DATA configuration file:

   SECURE_CTRLCONN PRIVATE

If you want to require that data is transferred integrity protected only, or both integrity and privacy protected, code the following statement in the client's FTP.DATA configuration file:

   SECURE_CTRLCONN SAFE

By default, data is transferred integrity protected only. However, the user can issue the cprotect private subcommand during the FTP session to change the data connection security level so that data is transferred both integrity and privacy protected. The user can also issue the cprotect safe subcommand to reset the data connection security level, so that data is transferred integrity protected only.

Port 990

The use of port 990 to implicitly protect FTP sessions was included in the early drafts of the IETF documents that describe how to use TLS with FTP, but has been removed from later drafts and from RFC 4217. For more information, see Information APAR II13516.

Port 990 is known as the protected port, or the TLSPORT. You can disable implicit security for port 990, or reassign the protected port, by coding the TLSPORT statement in the server's FTP.DATA configuration file.

Rule: If you start the FTP server on the protected port, you should code a SECUREIMPLICITZOS statement in the server's FTP.DATA file to specify when the server should expect the client to negotiate TLS security.

The FTP server can provide explicit TLS security on a different port by specifying the following definitions in FTP.DATA:

   EXTENSIONS AUTH_TLS
   SECURE_FTP REQUIRED
   SECURE_CTRLCONN PRIVATE
   SECURE_DATACONN PRIVATE
Steps for migrating the FTP server and client to use AT-TLS

Application Transparent Transport Layer Security (AT-TLS) is the best way to implement TLS security for the FTP server and client. AT-TLS provides additional functionality and performance for TLS secured connections.

Procedure

Perform the following steps to migrate from an existing configuration using TLS security for the FTP server and client to a configuration using AT-TLS:

For details about AT-TLS setup, see Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1093. For Policy Agent setup and AT-TLS policy statements, see z/OS Communications Server: IP Configuration Reference.

Requirements:

- The FTP server and client are controlling applications. For more information about controlling applications, see “Advanced application considerations” on page 1114.

  Code a TTLSEnvironmentAdvancedParms statement with the ApplicationControlled and SecondaryMap parameters; both parameters should specify the value On. The ApplicationControlled parameter allows FTP to start and stop TLS security on a connection. The SecondaryMap parameter enables active or passive data connections to use the AT-TLS policy that is used for the control connection. You do not need to code any additional TTLSRule statements for the data connections.

- The FTP server requires the HandshakeRole parameter with the value Server or ServerWithClientAuth to be coded on the TTLSEnvironmentAction statement. If the SECURE_LOGIN statement is coded in FTP.DATA with the parameters REQUIRED or VERIFY_USER, the HandshakeRole parameter value must be ServerWithClientAuth.

- The TTLSRule statement for the FTP server requires the Direction parameter with the value Inbound.

- The FTP client requires the HandshakeRole parameter with the value Client to be coded on the TTLSEnvironmentAction statement.

- The TTLSRule statement for the FTP client requires the Direction parameter with the value Outbound.

Guideline: The FTP server and client do not support SSLv2 when using TLSMECHANISM TLS. By default, AT-TLS does not enable SSLv2. SSLv2 should not be enabled in AT-TLS unless explicitly required by a remote system. If SSLv2 is required by a remote system, use a specific TTLSRule statement for the remote system that points to a TTLSConnectionAction statement enabling SSLv2.

2. Configure the FTP server and client to use AT-TLS by coding TLSMECHANISM ATTLS in FTP.DATA.

3. Use Table 32 on page 678 to migrate the existing FTP server and client configuration to AT-TLS.

   Remove the statements from FTP.DATA and code the AT-TLS equivalent statement.

<table>
<thead>
<tr>
<th>FTP.DATA statement</th>
<th>AT-TLS equivalent statement</th>
<th>AT-TLS policy statement</th>
</tr>
</thead>
<tbody>
<tr>
<td>KEYRING</td>
<td>Keyring</td>
<td>TTLSKeyRingParms -&gt;</td>
</tr>
<tr>
<td></td>
<td></td>
<td>TTLSEnvironmentAction</td>
</tr>
<tr>
<td>CIPHERSUITE</td>
<td>V3CipherSuites</td>
<td>TTLSCipherParms -&gt;</td>
</tr>
<tr>
<td></td>
<td></td>
<td>TTLSEnvironmentAction</td>
</tr>
<tr>
<td>TLSTIMEOUT</td>
<td>GSK_V3_SESSION_TIMEOUT</td>
<td>TTLSGskAdvancedParms -&gt;</td>
</tr>
<tr>
<td></td>
<td></td>
<td>TTLSEnvironmentAction</td>
</tr>
</tbody>
</table>

4. Use Table 33 on page 679 to migrate existing ciphers coded on CIPHERSUITE statements in FTP.DATA to AT-TLS TTLSCipherParms statements.
Table 33. Migrating existing ciphers

<table>
<thead>
<tr>
<th>CIPHERSUITES cipher</th>
<th>V3CipherSuites cipher</th>
<th>Hexadecimal value</th>
</tr>
</thead>
<tbody>
<tr>
<td>SSL_DES_SHA</td>
<td>TLS_RSA_WITH_DES_CBC_SHA</td>
<td>09</td>
</tr>
<tr>
<td>SSL_3DES_SHA</td>
<td>TLS_RSA_WITH_3DES_EDE_CBC_SHA</td>
<td>0A</td>
</tr>
<tr>
<td>SSL_NULL_MD5</td>
<td>TLS_RSA_WITH_NULL_MD5</td>
<td>01</td>
</tr>
<tr>
<td>SSL_NULL_SHA</td>
<td>TLS_RSA_WITH_NULL_SHA</td>
<td>02</td>
</tr>
<tr>
<td>SSL_RC2_MD5_EX</td>
<td>TLS_RSA_EXPORT_WITH_RC2_CBC_40_MD5</td>
<td>06</td>
</tr>
<tr>
<td>SSL_RC4_MD5</td>
<td>TLS_RSA_WITH_RC4_128_MD5</td>
<td>04</td>
</tr>
<tr>
<td>SSL_RC4_MD5_EX</td>
<td>TLS_RSA_EXPORT_WITH_RC4_40_MD5</td>
<td>03</td>
</tr>
<tr>
<td>SSL_AES_128_SHA</td>
<td>TLS_RSA_WITH_AES_128_CBC_SHA</td>
<td>2F</td>
</tr>
<tr>
<td>SSL_AES_256_SHA</td>
<td>TLS_RSA_WITH_AES_256_CBC_SHA</td>
<td>35</td>
</tr>
</tbody>
</table>

For example, for an FTP.DATA file that contains the following statements:

```
CIPHERSUITES SSL_AES_256_SHA
CIPHERSUITES SSL_3DES_SHA
CIPHERSUITES SSL_NULL_SHA
```

The equivalent TLSCipherParms statement:

```
TLSCipherParms
{  
V3CipherSuites TLS_RSA_WITH_AES_256_CBC_SHA
V3CipherSuites TLS_RSA_WITH_3DES_EDE_CBC_SHA
V3CipherSuites TLS_RSA_WITH_NULL_SHA
}
```

Traversing firewalls with SSL/TLS secure FTP

This topic describes functions in FTP that enable you to use FTP sessions that are secured by SSL/TLS using both network address translation (NAT) and filtering firewalls.

FTP requires the following TCP connections to transfer a file:

- Control connection
- Data connection

The control connection is established from the FTP client to the FTP server (default port 21). The data connection is established either from the FTP client to the FTP server, or from the FTP server to the FTP client; the direction is based on whether the client selects active mode or passive mode FTP.

- Active mode

  With active mode FTP, the data connection is established from the FTP server to the FTP client, which is the opposite direction of the control connection. The active mode data connection is established from a well-known port on the server host (default port 20) to an ephemeral port on the client host.

- Passive mode

  With passive mode FTP, the data connection is established from the FTP client to the FTP server, which is the same direction as the control connection. The data connection is established from an ephemeral port on the server host to an ephemeral port on the client host.

  Passive mode is also referred to as firewall-friendly FTP. An intranet FTP client connecting to an Internet FTP server can establish connections outbound through the company firewall, but not inbound through the firewall. With passive mode, both the control and data connections are established outbound through the firewall to the Internet.
The FTP client user decides which mode to use. Active mode is the default, but the user can usually change to passive mode. The z/OS FTP client user can switch between active and passive modes by issuing the LOCSITE subcommand with the NOFWFRIENDLY and FWFRIENDLY parameters.

Both active mode and passive mode FTP require the exchange of IP address and port information over the control connection. For active mode, the FTP client sends a PORT command specifying the IP address and port number to which the server must connect to establish the data connection. For passive mode, the FTP client sends a PASV command to the server, and the server replies with the IP address and port number to which the client should connect to establish the data connection.

Firewalls are often aware of FTP; they monitor the exchanges over the FTP control connection to learn the IP address and port number to which the data connection is to be established. NAT firewalls change the IP addresses on the PORT command or in the PASV reply. Filtering firewalls install dynamic filters based on the IP addresses and port information to enable the data connection to be established.

When you use SSL/TLS for FTP, the control connection is typically encrypted, so firewalls between the FTP client and server cannot see the data that is exchanged on the PORT command and the PASV reply. The firewalls cannot perform NAT successfully and they cannot install dynamic filters for the data connection, so the result is that your data connection very likely fails.

z/OS FTP includes the following support for functions that are specifically aimed at enabling FTP sessions through such firewalls:

- **Extended passive mode (EPSV)**
  Extended passive mode works very much like passive mode. Instead of sending a PASV command to the server, the client sends an EPSV command to the server. The server EPSV reply includes only a port number. The client always uses the same IP address for the data connection that it used for the control connection. A z/OS FTP client user switches to extended passive mode for IPv4 connections by issuing the LOCSITE subcommand with the EPSV4 and FWFRIENDLY parameters. These options can also be configured in the z/OS FTP client FTP.DATA file.

  EPSV allows sessions secured by SSL/TLS through NAT firewalls, but EPSV alone does not allow FTP sessions that are secured by SSL/TLS through firewalls that also implement dynamic filters.

- **The PASSIVEIGNOREADDR configuration option**
  This z/OS FTP client option directs the z/OS FTP client to ignore the IP address in the PASV reply and use only the port number when FTP is in passive mode. The client uses the same IP address that it used to log in to the FTP server for the data connection. A z/OS FTP client user enables this support by issuing the LOCSITE subcommand with the PASSIVEIGNOREADDR option. You can also configure this option in the z/OS FTP client FTP.DATA file.

  The PASSIVEIGNOREADDR configuration enables sessions secured by SSL/TLS through NAT firewalls in the same way that extended passive mode enables them, subject to the same limitations. You can use the PASSIVEIGNOREADDR option when the server does not support the EPSV command.

- **The PASSIVEDATAPORTS statement in FTP.DATA**
  This z/OS FTP server option enables you to define a range of port numbers that the z/OS FTP server can use in PASV and EPSV replies for passive mode data connections. If the PASSIVEDATAPORTS statement on the z/OS FTP server is used in combination with EPSV from the FTP client, the two techniques together allow FTP sessions secured with SSL/TLS through NAT firewalls that also implement static IP filters, assuming that the firewall administrators add static filter rules that allow FTP data connections access to one or more of the ports in the PASSIVEDATAPORTS range.

- **The clear command channel (CCC) command**
  The CCC command can be used on a control connection secured by SSL/TLS to disable SSL/TLS security. The control connection starts out as secured by SSL/TLS, and stays that way until a user ID and password or password phrase have been exchanged with the server. At that point, the FTP client can send a CCC command to the server, which disables SSL/TLS for the control connection and enables PORT commands and replies to PASV and EPSV commands to flow in the clear on the control connection. When these exchanges occur in the clear, firewalls between the FTP client and FTP server
can perform NAT processing and dynamic filter processing as if the connection is not secured with SSL/TLS. The CCC command does not turn off security for the data connection.

To enable the z/OS FTP server to accept the CCC command, configure TLSRFCLEVEL RFC4217 or TLSRFCLEVEL CCCNONOTIFY at the FTP server.

To enable the z/OS FTP client to support the CCC command, configure TLSRFCLEVEL RFC4217 or TLSRFCLEVEL CCCNONOTIFY at the FTP client, matching the client TLSRFCLEVEL value to the server TLSRFCLEVEL value. You can use the LOCSITE subcommand to change the TLSRFCLEVEL value. When TLSRFCLEVEL RFC4217 or TLSRFCLEVEL CCCNONOTIFY is configured at the z/OS FTP client, use the CCC subcommand after logging in to the FTP server to send a CCC command to the FTP server.

The support that you use depends on your network topology. The following scenarios are a few selected scenarios to consider for making sure that FTP sessions secured by SSL/TLS can get through your network. The scenarios assume that z/OS is at least one of the endpoints of the secure FTP session. The partner endpoint can be z/OS or any secure FTP product on the market that supports the same RFC levels as z/OS (primarily RFC 4217).

- Your firewall performs NAT only (minimal or no filtering), your FTP client is in a private network behind the NAT firewall, and the FTP server is in a public network such as the Internet, as shown in Figure 88 on page 681.

  ![Figure 88. SSL/TLS-secured FTP session scenario 1](image1.png)

  Normal passive mode (PASV) usually works in such a scenario. Extended passive mode (EPSV) also works, but is generally not required.

- Your firewalls perform NAT only (minimal or no filtering), your FTP client is in one private network, your FTP server is in another private network, and you have two NAT firewalls between the client and server networks that are connected over a public network, as shown in Figure 89 on page 681.

  ![Figure 89. SSL/TLS-secured FTP session scenario 2](image2.png)

  If your partner's secure FTP product supports extended passive mode, use extended passive mode (EPSV) from the FTP client. If the FTP client is the z/OS FTP client and the partner's secure FTP server product does not support EPSV, configure the PASSIVEIGNOREADDR option at your z/OS FTP client to simulate EPSV processing.

- Your firewall performs NAT and static filtering (predefined filter rules). Your FTP client is in a private network behind the NAT firewall, with a z/OS FTP server that is in a public network such as the Internet, as shown in Figure 90 on page 681.

  ![Figure 90. SSL/TLS-secured FTP session scenario 3](image3.png)

  Use the PASSIVEDATAPORTS statement in the z/OS FTP server's FTP.DATA file to predefined a range of port numbers that the z/OS FTP server can use for data connections. Your firewall administrator needs...
to add static filter rules for the passive data port range. Normal passive mode (PASV) usually works in such a scenario, but extended passive mode (EPSV) can also be used if supported by the FTP client.

• Your firewalls perform NAT and static filtering (predefined filter rules). Your FTP client is in one private network, your z/OS FTP server is in another private network, and you have two NAT firewalls between the client and server networks that are connected over a public network, as shown in Figure 91 on page 682.

![Figure 91. SSL/TLS-secured FTP session scenario 4](image)

Use the PASSIVEDATAPORTS statement in the z/OS FTP server’s FTP.DATA file to predefine a range of port numbers that the z/OS FTP server can use for data connections. Your firewall administrator needs to add static filter rules for the passive data port range. In this case, you must use extended passive mode. If the FTP client does not support extended passive mode, this scenario is not likely to work.

• Your firewalls perform dynamic filtering (with or without NAT) and your partner’s secure FTP product supports the CCC command, as shown in Figure 92 on page 682.

![Figure 92. SSL/TLS-secured FTP session scenario 5](image)

Use the CCC command from the FTP client. This scenario is not likely to work without CCC command support.

• You do not know what your firewalls do and your partner’s secure FTP product does support the CCC command, as shown in Figure 93 on page 682.

![Figure 93. SSL/TLS-secured FTP session scenario 6](image)

Use the CCC command from the FTP client. This scenario is not likely to work without CCC command support.

Firewalls reject FTP sessions secured by SSL/TLS in the following additional scenarios:

• Some firewalls are known to apply various validity checks on the FTP control connection data stream. One known check verifies that all interactions on the FTP control connection are terminated with an ASCII newline (NL) character. Most of these checks fail when the control connection is secured with SSL/TLS, because the data is encrypted. If you use the information in this topic and still run into problems establishing FTP sessions secured by SSL/TLS through firewalls, verify with your firewall administrators whether your firewalls implement such validity checks on the FTP control connection, and consider disabling those validity checks.

• Some firewalls are known to disable active mode data connections by default, and block all active mode data connections. Use passive mode or extended passive mode FTP instead.

• Many firewalls monitor activity on TCP connections and terminate connections that are idle for a certain period of time. During a large data transfer over an FTP data connection, the FTP control connection is idle. To avoid having firewalls terminate idle FTP connections, consider coding the FTPKEEPALIVE statement in the z/OS FTP.DATA file for the client or the server. For more information about the FTPKEEPALIVE statement, see “Configuring PROFILE.TCPIP for FTP” on page 638.
Db2 and JES

The following statements are used when FTP interfaces with Db2 and JES, respectively. For more information, see z/OS Communications Server: IP Configuration Reference and the optional steps in this information.

- DB2®
- DB2PLAN
- JESGETBYDSN
- JESINTERFACELEVEL
- JESLRECL
- JESPUTGETTO
- JESRECFM
- SPREAD and SQLCOL

Configuring the optional FTP user exits

This information describes exit routines that you can code and install. For information about coding user exits and for a list of sample user exits, see z/OS Communications Server: IP Configuration Reference.

Tip: You can find the sample user exit routines in SEZAINST.

The FTPSMFEX user exit (for the FTP server)

Note the FTP server SMF user exit is called before an SMF type 118 record that contains information about an FTP server session is written to the SYS1.MANx data set. The user exit allows site specific modifications to the record and controls whether the record is written to the SYS1.MANx data set.

Note that the exit is called only for type 118 records. SMF type 119 FTP records must use the system-wide SMF user exits (IEFU83, IEFU84, and IEFU85) to obtain this same functionality. For information on these SMF user exits, see z/OS MVS System Management Facilities (SMF).

The FTCHKIP user exit (for the FTP server)

The FTCHKIP user exit is called when a user attempts to log in to the FTP server or when a user issues the OPEN subcommand to establish a new connection. The following information is passed to the exit:

- Client IP address *
- Client port number *
- Server IP address *
- Server port number *
- The socket address structure of the client's control connection
- The socket address structure of the server's control connection
- Session instance identifier

Note: Fields above marked with an asterisk (*) are valid only for IPv4 addresses, including IPv4-mapped IPv6 addresses.

An installation can use this exit to determine if a particular IP address or port number is allowed to access the FTP site. If the connection is denied by the user exit, the following message is sent to the user:

421 User Exit rejects open for connection
The FTCHKPWD user exit (for the FTP server)

The FTCHKPWD user exit is called immediately after the user enters the password, password phrase, or email address while logging in to the FTP server. The following information is passed to the exit:

- The user ID
- The user password
  This field will be set to an asterisk (*) if an email address is entered instead of a password.
  This field will be set to the first eight characters of the password phrase if the user provides a password phrase instead of a password. The entire password phrase is passed to this exit as another parameter.
- A userdata buffer
  If an email address is entered to log in, the userdata buffer contains the email address.
- The number of incorrect passwords or password phrases entered during this session
- The socket address structure of the client's control connection
- The socket address structure of the server's control connection
- Session instance identifier
- The user password or password phrase used to log in to the FTP server

The exit can be used to restrict access to a site based on user ID, password or password phrase, number of bad passwords or password phrases entered, or anything in the socket address information for the client or server. If the login is denied by the user exit, the following reply is sent to the user:

```
530 PASS command failed
```

Result: If you coded ACCESSERRORMSGs TRUE in FTP.DATA, an additional 530 reply with information about why the PASS command failed might precede the reply above.

The FTCHKCMD user exit (for the FTP server)

The FTCHKCMD user exit is called whenever the server receives an FTP command. The following information is passed to the user exit:

- The user ID
- The FTP command to be processed
- The command's arguments
- The directory type (MVS or HFS)
- The FILETYPE (SEQ, JES, or SQL)
- The current working directory
- A buffer to hold a modified argument string
- A buffer to hold a 500 reply extension to explain why the exit denied the request
- The socket address structure of the client's control connection
- The socket address structure of the server's control connection
- Session instance identifier
- A 256-byte scratchpad buffer

The user exit enables an installation to modify the arguments of an FTP command or to deny a user from issuing the command. For example, if the server receives a LIST * command, the exit can either deny the command or modify it to LIST 'USER1.*'. If the user exit denies the request by this user to issue this command, one or both of the following replies will be sent to the user. The first reply is optional and is sent only if the user exit returns a string in the 500 reply extension buffer.

```
500-UX-buffercontents
500 User Exit denies Userid userid from using Command command
```
The **FTCHKJES user exit (for the FTP server)**

FTCHKJES is called if the server is in FILETYPE=JES mode and the client tries to submit a job. The following information is passed to the exit:

- The user ID
- A buffer containing the current JCL statement
- Size of statement in the buffer
- JESLrecl value
- Number of this buffer in current series
- Bytes transferred so far (including this buffer)
- Client identifier (see also session instance identifier)
- JESRecfm value
- FTCHKJES exit-specific workarea (4 bytes)
- The socket address structure of the client's control connection
- The socket address structure of the server's control connection
- Session instance identifier
- A 256-byte scratchpad buffer

The exit can allow or refuse the job to be submitted to the JES internal reader based on any information passed to the exit. For example, the exit can look for a USER= parameter on the JOB statement and check it against the client's user ID. If the remote job submission is denied, the exit sends the user the following reply:

```
550 User Exit refuses this job to be submitted by userid
```

The **FTPOSTPR user exit (for the FTP server)**

FTPOSTPR is called after execution of the FTP commands RETR, STOR, STOU, APPE, DELE, and RNTO. The following information is passed to the exit:

- The user ID
- Client IP address *
- Client port number *
- The directory type (MVS or HFS)
- The current working directory
- The FILETYPE (SEQ, JES, or SQL)
- Most recent reply code number
- Most recent reply text string
- Current FTP command
- Current CONDDISP setting
- Close reason code
- Name of data set or z/OS UNIX file retrieved or stored
- Bytes transferred
- The socket address structure of the client's control connection
- The socket address structure of the server's control connection
- Session instance identifier
- A 256-byte scratchpad buffer
- The 1-byte description of the confidence-of-successful-completion level assigned to this file transfer
Notes:
1. Fields above marked with an asterisk (*) are valid only for IPv4 addresses, including IPv4-mapped IPv6 addresses.
2. The directory type reflects the current working directory. The MVS data set or z/OS UNIX file that is retrieved or stored can be located in a different type of directory.

The exit allows for post processing at the termination of data transfer functions within the server.

The EZAFCCMD user exit (for the FTP client)
The EZAFCCMD user exit is called by the FTP client before an FTP command is sent to the FTP server. The following information is passed to the exit:

- The number of parameters that are passed to the exit
- The TCP connection ID
- The remote user ID
- The FTP command to be processed
- The arguments of the command
- The directory type (MVS or HFS)
- The z/OS UNIX file type (FILE or FIFO)
- The current local directory
- The fully qualified MVS data set name or z/OS UNIX absolute path name of the client
- The current configuration of the FTP client
- The socket address structure of the control connection for the client
- The socket address structure of the control connection for the server
- The socket address structure of the connection for the SOCKS server
- FTP client application data for the control connection
- A buffer to hold a modified argument string
- A buffer to hold a 71-byte message from the user exit

This exit can inspect an FTP command, modify the arguments of an FTP command, reject an FTP command, or end the FTP client before the command is sent to the server. For example, if the client is sending a LIST * command, the exit can inspect the LIST command, change the command argument to LIST 'USER11.*', reject the LIST command, or end the FTP client.

Restrictions:
- This user exit cannot end the client when the QUIT command is generated by the QUIT subcommand, but the client does end as part of QUIT subcommand processing.
- This user exit cannot reject the QUIT command that is generated by the QUIT subcommand or by the CLOSE subcommand.
- This user exit cannot change the FTP command, but can change the arguments of the FTP command.
- This user exit cannot modify the arguments of the AUTH, EPRT, EPSV, MODE, PBSZ, PORT, PROT, REST, SITE, STRU, TYPE, and XLMT commands.
- This user exit cannot inspect the PASS or ACCT command arguments, but can modify the arguments of these commands.
- This user exit cannot inspect or modify the ADAT command arguments.
- This user exit cannot modify the RETR or STOR command arguments when the transferred MVS data set is a load module.

For more information about the EZAFCCMD user exit, see z/OS Communications Server: IP Configuration Reference.
The EZAFCREP user exit (for the FTP client)

The EZAFCREP user exit is called when the FTP client receives a single-line reply or one line of a multiple-line reply from the server over the control connection. The following information is passed to the user exit:

- The number of parameters that are passed to the user exit
- The TCP connection ID
- The FTP server reply line that is received by the FTP client
- FTP client application data for the current control connection
- A 71-byte buffer to hold a message from the user exit

Use the EZAFCREP user exit to inspect the FTP server reply or to end the FTP client after the FTP client receives a particular line of the reply from the server. If the user exit ends the FTP client, one or both of the following messages are displayed to the user. Message EZA1556I is optional and is displayed only when the user exit returns text in the 71-byte buffer.

EZA1556I EZAFCREP message: message text provided by user exit routine
EZA1546I User exit EZAFCREP module modname ended the FTP client - exit reason code
x 'hexadecimal-rsncode' (decimal-rsncode)

Restrictions:

- This user exit cannot modify FTP server replies.
- This user exit cannot end the client when the reply is generated by the QUIT subcommand, but the client does end as part of QUIT subcommand processing.
- This user exit cannot end the client when the input to the exit is a reply with a reply code in the range 100–199.

For more information about the EZAFCREP user exit, see z/OS Communications Server: IP Configuration Reference.

Customizing the FTP-to-JES interface for JESINTERFACELevel 2 (optional)

If FTP.DATA does not change the JESINTERFACELEVEL to 2, the FTP server uses the JES interface provided in releases prior to CS for OS/390 V2R10. At this level, the FTP user is allowed to submit jobs to JES, retrieve held output matching their logged-in user ID plus one character, and delete held jobs matching their logged-in user ID plus one character.

If JESINTERFACELevel is set to 2, FTP users have the ability to retrieve and delete any job in the system permitted by the System Authorization Facility (SAF) resource class JESSPOOL. For that reason, JESINTERFACELevel=2 should be specified only if the appropriate JES and SDSF security measures are in place to protect access to JES output. The SAF controls used for JESINTERFACELevel=2 are essentially a subset of those used by SDSF. Therefore, if an installation has customized SAF facilities for SDSF, they are configured for FTP level 2.

Note: You are not required to have SDSF to use JESINTERFACELEVEL 2. If you do not use SDSF, you need to create SAF profiles. Both SDSF and JESINTERFACELEVEL 2 use the same SAF profile names.

Before customizing the FTP-to-JES interface, complete JES customization. For example, JESJOBS is an SAF class that controls which users can submit jobs to JES. JESSPOOL is the SAF class that controls which users can access output jobs. Customize these SAF classes before beginning customization of the FTP-to-JES interface.

JESSPOOL defines resource names as <nodeid>.<userid>.<jobname>.<Dsid>.<dsname>. An FTP user can delete an output job if they have UPDATE access to the resource that matches their nodeid, userid, and job name. If the FTP user has READ access to the resource, they can list, retrieve, or GET the job output. For more information on JES security, see z/OS JES2 Initialization and Tuning Guide. For more information on the SAPI interface, see z/OS MVS Using the Subsystem Interface.

There are three filters used by the FTP server to control the display of jobs:

- JESSTATUS
• JESOWNER
• JESJOBNAME

SDSF resources are employed for this.

JESSTATUS can be changed by an FTP user with the SITE command to filter jobs in INPUT, ACTIVE, or OUTPUT state. The SDSF resources checked for these states are ISFCMD.DSP.INPUT.jesx, ISFCMD.DSP.ACTIVE.jesx, and ISFCMD.DSP.OUTPUT.jesx, respectively. At login time (USER command), the default value is set to ALL if READ access is allowed to all three classes. Otherwise it attempts to set it to OUTPUT, ACTIVE, and then INPUT if the appropriate READ access is allowed. If no READ access is allowed to any of the classes, JESSTATUS is set to OUTPUT but JESOWNER and JESJOBNAME cannot be changed from the default. In this way, SAF controls can be put in place to limit FTP users to whatever status of jobs an installation requires.

At login time, JESOWNER will have the value of the logged-in user ID. Authority to change JESOWNER is obtained through READ access to RACF profile ISFCMD.FILTER.OWNER. An FTP user who has READ access to ISFCMD.FILTER.OWNER will be allowed to change the JESOWNER parameter with the SITE command.

At login time, JESJOBNAME will have the value of the logged-in user ID plus an asterisk (*). Authority to change JESJOBNAME is obtained through READ access to RACF profile ISFCMD.FILTER.PREFIX. An FTP user who has READ access to ISFCMD.FILTER.PREFIX will be allowed to change the JESJOBNAME parameter with the SITE command.

For example, to allow all users except USER1 to be allowed to change JESOWNER enter the following commands:

```
SETROPTS CLASSACT(SDSF) REFRESH
RDEFINE SDSF (ISFCMD.FILTER.OWNER) UACC(READ)
PERMIT ISFCMD.FILTER.OWNER ACCESS(NONE) CLASS(SDSF) ID(USER1)
SETROPTS CLASSACT(SDSF) REFRESH
```

For more information on SDSF security, see z/OS SDSF Operation and Customization.

### Configuring the FTP server for anonymous FTP (optional)

You can configure the FTP server to allow users to log in anonymously. A user logs in anonymously by logging in as anonymous instead of as a user ID defined to the system. To enable users to log in anonymously, code the ANONYMOUS statement in the server FTP.DATA data set.

You can specify three levels of anonymous support on the ANONYMOUSLEVEL statement.

- **ANONYMOUSLEVEL 1**
  That is, the ANONYMOUS statement is supported. If no operands are specified on the ANONYMOUS statement, the anonymous user needs no password and has access to MVS data sets and the z/OS UNIX file system.

- **ANONYMOUSLEVEL 2**
  You should not specify ANONYMOUSLEVEL 2; ANONYMOUSLEVEL 2 is provided for migration purposes only. Consider ANONYMOUSLEVEL 3 if ANONYMOUSLEVEL 1 does not meet your anonymous login security requirements.

- **ANONYMOUSLEVEL 3**
  ANONYMOUSLEVEL 3 is the default. If you specify ANONYMOUSLEVEL 3, the anonymous user cannot issue the USER command to leave anonymous mode, nor can another user issue USER anonymous to enter anonymous mode.

If you specify ANONYMOUSLEVEL 3 and STARTDIRECTORY HFS in FTP.DATA, the following rules apply:

- The anonymous user’s z/OS UNIX file system access is restricted to the anonymous user’s home directory and home directory subtrees. The anonymous user’s home directory is the home directory...
of the user ID coded on the ANONYMOUS statement or the home directory of the user ID ANONYMO if you code the ANONYMOUS statement without a user ID.

- You must create an anonymous directory structure in the z/OS UNIX file system. See “Creating an anonymous directory structure in the z/OS UNIX file system” on page 690 for more information.

If you specify ANONYMOUSLEVEL 3 and STARTDIRECTORY MVS in FTP.DATA, you must create a shadow copy of the /usr/sbin/ftpdns path and file under the home directory of the anonymous user in the z/OS UNIX file system. For more information, see step 2 in “Creating an anonymous directory structure in the z/OS UNIX file system” on page 690.

The ANONYMOUSLEVEL 3 server recognizes additional statements that restrict the anonymous user's access to FTP resources. The following statements are ignored when ANONYMOUSLEVEL is 1 or 2:

- ANONYMOUSFILEACCESS allows the system programmer to preclude access to either the z/OS UNIX file system or MVS data sets.
- ANONYMOUSFILETYPEJES, ANONYMOUSFILETYPESQL, and ANONYMOUSFILETYPESEQ control whether the anonymous user can set file type JES, SQL, or SEQ, respectively.
- ANONYMOUSHFSFILEMODE defines the mode bits used for files written to the z/OS UNIX file system.
- ANONYMOUSHFSDIRMODE defines the mode bits used for directories created in the z/OS UNIX file system.

When ANONYMOUSLEVEL is set to 3, the user's email address is requested in lieu of a password in the following situations:

- ANONYMOUS is specified without any parameters.
- ANONYMOUS is specified with user ID/password.
- ANONYMOUS is specified with user ID/SURROGATE.

You can control the degree of verification of the email address that an anonymous user enters as a password by using the EMAILADDRCHECK keyword in FTP.DATA. See z/OS Communications Server: IP Configuration Reference for details about the EMAILADDRCHECK keyword. The email address entered is logged to the syslog daemon and is also passed to a user exit routine, FTCHKPWD, for user processing.

The FTP server can be defined to process users without passwords by using the ANONYMOUS SURROGATE support. In order to support this, ANONYMOUSLEVEL must be set to 3 in FTP.DATA on the server and BPX.SRV surrogate must be defined in RACF.

z/OS UNIX uses profiles defined to the RACF SURROGAT class to authorize the server to act as a surrogate of a client. Profiles defined to the SURROGAT class are of the form:

```
BPX.SRV.<userid>
```

in which <userid> is the MVS user ID of the user that the server will support without a password.

The following steps are for a sample user ID of the FTP daemon (the user ID associated with the FTP started task procedure) called FTPD with the ability to support user ID GUEST without a password. As you add more servers, you will need to follow similar procedures.

1. Activate the SURROGAT class support in RACF:

   ```
   SETROPTS CLASSACT(SURROGAT)
   ```

   This has to be done only once on the system. The SURROGAT class may already have been set up on your system. If a daemon or server you are running will be using the SURROGAT support heavily, consider using the RACLIST command to keep the SURROGAT profiles in storage. The following example shows how to cache the SURROGAT profiles in storage:

   ```
   SETROPTS RACLIST(SURROGAT)
   ```
2. If the SURROGAT profile is in the RACLIST, any changes to the SURROGAT profiles must be followed by a REFRESH command. To create the SURROGAT class profile for user ID GUEST, issue:

```
RDEFINE SURROGAT BPX.SRV.GUEST UACC(NONE)
SETROPTS RACLIST(SURROGAT) REFRESH
```

A similar SURROGAT profile is required for each user ID that a server must support without a password.

3. To permit the user ID of the FTP daemon (the user ID associated with the FTP started task procedure), FTPD, to create a security environment for user ID GUEST, issue the PERMIT command:

```
PERMIT BPX.SRV.GUEST CLASS(SURROGAT) ID(FTPD) ACCESS(READ)
SETROPTS RACLIST(SURROGAT) REFRESH
```

Creating an anonymous directory structure in the z/OS UNIX file system

The sample shell script, ftpandir.scp, will create an anonymous directory structure for you, containing required and optional structures. Or, a superuser can create the anonymous directory structure. In this topic, the steps a superuser would follow to create an anonymous directory structure are outlined.

For the following steps, assume that the RACF user ID that is used when an anonymous user logs in is called GUEST, that the HOME directory in that user's OMVS segment in RACF is /u/guest, and that FTP.DATA contains a statement similar to this: ANONYMOUS GUEST

1. Create a bin subdirectory in the anonymous root containing the executable files ls and sh. This is a required directory. ls can be copied from the standard directory. sh is part of the standard MVS search order, so you need only create an empty file with the sticky bit.

The following example shows how to create ls and sh in the user GUEST’s home directory:

```
====> cd /u/guest
====> mkdir bin
====> chmod 711 bin
====> cd bin

====> cp /bin/ls ls
====> chmod 711 ls
====> touch sh
====> chmod 711 sh
====> chmod +t sh
```

An `ls -al` command should give the following results. Owner and group attributes may be different in your system.

```
# ls -al
total 280
drwxr-xr-x 2 USER22 0 8192 Sep 21 17:39 .
drwxr-xr-x 7 USER22 0 8192 Nov  1 14:44 ..
-rwxr-xr-x 1 USER22 0 126976 Sep 21 17:39 ls
-rwxr-xr-t 1 USER22 0 0 Sep 21 17:39 sh
```

2. Create a usr/sbin subdirectory of the anonymous root containing the executable file ftpdns. This is a required subdirectory. The file ftpdns can be empty with the sticky bin on.

The following example is for anonymous user GUEST:

```
====> cd /u/guest
====> mkdir usr
====> chmod 711 usr
====> cd usr

====> mkdir sbin
====> chmod 711 sbin
====> cd sbin

====> touch ftpdns
====> chmod 711 ftpdns
```

```
690 z/OS Communications Server: IP Configuration Guide
```
If you do not configure the subdirectories, bin and usr/sbin, and their contents correctly, the FTP server will not be able to accept anonymous logins and message EZYFT731 will be displayed.

3. Create a dev subdirectory within the anonymous root. This is a required subdirectory. A null file is created in this directory and used during the open of syslog.

The following example is for anonymous user GUEST:

```bash
  ====> cd /u/guest
  ====> mkdir dev
  ====> chmod 711 usr
```

If you do not have the dev subdirectory, syslog might not open correctly. Messages such as EZA2830I will not be logged out correctly.

4. Set up the public directory structure. This is a required directory.

This is the directory structure into which you place files that can be downloaded by the anonymous FTP user. It does not have to be named pub; it can be any name you choose. A general convention for anonymous FTP sites is to call it pub:

```bash
  ====> cd /u/guest
  ====> mkdir pub
  ====> cd pub
```

If you want to structure the files you allow to be accessed, you can create multiple subdirectories underneath this directory.

For simplicity, assume a single level directory, the pub directory. Into this directory you copy the files you want to allow the anonymous user to download:

```bash
  ====> cp /x/y/z/prodinfo1.txt prodinfo1.txt
  ====> cp /x/y/z/prodinfo2.txt prodinfo2.txt
  ====> cd ..
```

Make sure that the permission bits are set correctly by using the following shell command when executed in the /u/guest directory. This will set the permission bits of all files in the pub directory and its subdirectories to 755:

```bash
  ====> chmod -R 755 pub
```

If your system does not require an incoming or extract directory, the system is configured for anonymous FTP. An `ls -al` command of the pub directory should give the following results:

```
drwxr-xr-x  3 IBMUSER SYS1 8192 May 13 21:15 .
drwxr-xr-x  6 IBMUSER SYS1 8192 May 20 14:51 ..
rwxr-xr-x  1 IBMUSER SYS1 12 May 11 12:41 prodinfo1.txt
-rwxr-xr-x  1 IBMUSER SYS1 12 May 11 12:41 prodinfo2.txt
```

5. Set up an incoming directory (optional).

If you want anonymous users to be able to upload files to your FTP server, you need some additional setup. The objective is to allow an anonymous user to upload a file, but not to allow another anonymous user to download or even be aware of the existence of the file until after an administrative user has verified that the content of the file is acceptable. You do not want your FTP server site to become a store-and-forward site for files of questionable ethical content.

Positioned at the /u/guest directory, a superuser issues the following shell command:

```bash
  ====> cd /u/guest
  ====> mkdir incoming
  ====> chmod 733 incoming
```

It does not have to be named incoming; it can be any name you choose. A general convention for anonymous FTP sites is to call it incoming.

The 733 permission bits means that a non-superuser cannot list the content of the incoming directory, but can write a file to it. Because the FTP server enforces a UMASK of 777 when an anonymous user
logs in, these files will be written with permission bits 000, which means that they cannot be accessed by the anonymous user or by any other user except a superuser.

An FTP client user can usually change the UMASK value with a SITE UMASK command or the user can change the permission bits of files they own through a SITE CHMOD command.

If you define ANONYMOUSLEVEL 3, you can use the ANONYMOUSHFSDIRMODE keyword to set the permission bits of any directory created by an anonymous user, and the ANONYMOUSHFSFILEMODE to set the permission bits of any file created by an anonymous user.

If you do allow anonymous users to store files on your FTP server, you should ensure that the directory into which these files are stored is a separate z/OS UNIX file system that can fill up without impacting other work on your z/OS system. The best way to do that is to allocate the /u/guest/incoming directory in its own z/OS File System, HFS data set, or Network File System. If an anonymous user uploads large amounts of data to the incoming directory, only this separate z/OS UNIX file system will be filled up. Filling this separate z/OS UNIX file system prevents other anonymous users from storing new files on the server, but will not affect other functions on your system. At a minimum, you should make sure that the incoming directory is not located on the same physical device as your /tmp directory.

6. Set up the extract directory (optional).

If you need to make files available to certain anonymous users, but not to everyone, you can create a directory that cannot be listed, but files in it can be downloaded if the anonymous user knows the name of the file.

Positioned at the /u/guest directory, a superuser issues the following shell commands:

```bash
    ==> cd /u/guest
    ==> mkdir extract
    ==> chmod 711 extract
```

It does not have to be named extract; it can be any name you choose. A general convention for anonymous FTP sites is to call it extract.

A superuser can then copy files into this directory, ensure they have permissions of 755, inform the intended anonymous user of the file name, and that user can then log on as anonymous and retrieve the file.

An `ls -al` command at the /u/guest location should give the following result, if you created all four subdirectories:

<table>
<thead>
<tr>
<th>Mode</th>
<th>User</th>
<th>Group</th>
<th>Name</th>
<th>Size</th>
<th>Date</th>
<th>Time</th>
<th>Link</th>
</tr>
</thead>
<tbody>
<tr>
<td>drwxr-xr-x</td>
<td>IBMUSER</td>
<td>SYS1</td>
<td>.</td>
<td>8192</td>
<td>May 20</td>
<td>14:51</td>
<td>.</td>
</tr>
<tr>
<td>dr-xr-xr-x</td>
<td>IBMUSER</td>
<td>SYS1</td>
<td>..</td>
<td>0</td>
<td>Jun 10</td>
<td>15:43</td>
<td>..</td>
</tr>
<tr>
<td>drwxr-xr-x</td>
<td>IBMUSER</td>

<td>SYS1</td>
<td>incoming</td>
<td>8192</td>
<td>May 25</td>
<td>09:35</td>
<td>incoming</td>
</tr>
<tr>
<td>drwx-xr-x</td>
<td>IBMUSER</td>
<td>SYS1</td>
<td>pub</td>
<td>8192</td>
<td>May 13</td>
<td>21:15</td>
<td>pub</td>
</tr>
</tbody>
</table>

Configure the welcome banner page, login, and directory message (optional)

The FTP server provides support to enable FTP administrators to provide useful information about the site to FTP users. The following FTP.DATA statements are available:

- BANNER
- LOGINMSG
- ANONYMOUSLOGINMSG
- MVSINFO
- ANONYMOUSMVSINFO
- HFSINFO
- ANONYMOUSHFSINFO
You can use the LOGINMSG statement in FTP.DATA to point to a set of messages displayed when a known user logs in to FTP. Similarly, ANONYMOUSLOGINMSG can point to a set of messages displayed when an anonymous user logs in to FTP.

You can use the MVSINFO statement to point to a set of messages displayed when a known user changes the working directory to a particular MVS data set path. Likewise, use the ANONYMOUSMVSINFO statement to point to a set of messages displayed when an anonymous user changes working directory to a particular MVS data set path.

You can use the HFSINFO statement to point to a set of messages displayed when a client changes the working directory to a particular z/OS UNIX directory. Likewise, use the ANONYMOUSHFSINFO statement to point to a set of messages displayed when an anonymous user changes working directory to a particular z/OS UNIX directory.

**Using magic cookies to represent information**

The content of all the informational messages may include a predefined set of magic cookies, which are substituted by the FTP server before the data is sent to the FTP client. The following magic cookies are supported:

- %T — Local time
- %C — Current working directory
- %E — The email address of the FTP server administrator
- %R — Remote host name
- %L — Local host name
- %U — Username (logged in user)

If %R is used, a long delay in login processing might occur as the FTP server will issue a DNS query to resolve the remote host IP address. In order to use %E, the ADMINEMAILADDR keyword must be specified in the server FTP.DATA configuration file.

**Configuring the FTP server to log session (user ID) activity**

You can configure the FTP server to write log messages for trace activity related to individual sessions by coding the FTPLOGGING or ANONYMOUSFTPLOGGING statements in FTP.DATA. If you have configured syslogd for FTP, the log messages appear in syslog.

Table 34 on page 693 shows the FTP log message written for various activities. You can identify an FTP log message by the ID=sessionID parameter in the message. Each login session is assigned a session ID that can be used to identify all log messages related to that session. For more information about EZYFxxxx messages, see z/OS Communications Server: IP Messages Volume 3 (EZY).

### Configuring to send detailed login failure replies to an FTP client (optional)

The FTP server returns minimal information to the client when the PASS command fails. However, you can configure the FTP server to send additional information by coding ACCESSERRORMSGS TRUE in FTP.DATA. This directs the server to reply to the client with detailed login failure data. The reply might report server errors, such as failing function calls with diagnostic return codes. It might report user errors, such as an expired or incorrect password or password phrase, an unknown user ID, or a revoked user ID. You should not code ACCESSERRORMSGS TRUE in FTP.DATA if you do not want to share this type of information with users logging in to FTP.

You can capture the same information in syslog by coding FTPLOGGING TRUE and ANONYMOUSFTPLOGGING TRUE in FTP.DATA. You can also turn on the DEBUG option called ACC to log the error messages in the syslog. For more information on coding FTP.DATA statements, see z/OS Communications Server: IP Configuration Reference.

Install the SQL query function (optional) and access the Db2 modules

To use FTP to perform SQL queries, bind a plan that allows FTP to invoke the package EZAFTPMQ in collection EZAFTPMQ, and grant execution privileges for that plan to PUBLIC. You can specify the name of the plan using the DB2PLAN keyword in FTP.DATA, or the default is EZAFTPMQ. This FTP facility performs only SELECT operations on the Db2 tables; it does not perform UPDATE, INSERT, or DELETE operations.

**Requirement:** If secondary authorization for SQL queries is required, you must modify the DSN3SATH sample exit shipped by Db2. The exit returns the primary AUTHID for requests that originate from the FTP server.

The following sample job is provided in the FTOEBIND member of the SEZAINST data set; you can use it to enable the FTP server and client to perform SQL queries.

```plaintext
//FTPBIND EXEC PGM=IKJEFT01,DYNAMNBR=20
//STEPLIB DD DSN=xxxxxx.DSNLOAD,DISP=SHR
//SYSTSPRT DD SYSOUT=*  
//SYSPRINT DD SYSOUT=*  
//SYSTSIN DD *  
//DSN SYSTEM(xxx)  
```

Accessing Db2 modules

The FTP server or client loads 3 Db2 modules into storage to perform an SQL query. These modules are:

- DSNALI
- DSNHLI2
- DSNTIAR

The modules are usually found in the Db2 load library with the suffix DSNLOAD. The Db2 administrator or system programmer should add the DSNLOAD library to the LINKLIST to ensure FTP has access to this library.

Another way to ensure access is to add the DSNLOAD library to the FTP STEPLIB. For the FTP server this means the JCL used to start the FTP server has a STEPLIB DD statement referring to the DSNLOAD library or, if the FTP daemon is started from the z/OS shell, the STEPLIB environment variable is set. For the FTP client, this means a TSO CLIST must allocate the DSNLOAD library as the STEPLIB.

If the FTP client is to be run from a batch job to perform SQL queries, the DSNLOAD library must be added to the STEPLIB DD statement for the batch job.

Usage notes:
To allow FTP access to multiple levels of Db2, link to the libraries that contain the lowest level of Db2 to be accessed.

FTP.DATA updates for SQL query function

To obtain FTP.DATA updates for the SQL query function, follow these steps:

1. Set the FTP.DATA DB2 statement to specify the name of the Db2 subsystem.
2. Set DB2PLAN to specify the Db2 plan to be used by the FTP server.
3. Set the SPREAD statement to specify whether SQL output is in spreadsheet format.
4. Set SQLCOL to specify the column headings of the output data.
Verifying the FTP server

If FTP is in the autolog list and the TCP/IP address space is restarted, FTP should start automatically. For other cases, it should be started manually. To do this, go to the MVS console and enter the following command:

```
S FTPD
```

**Note:** This command assumes the FTP procedure name is FTPD.

If the FTP server startup is complete, the following message should be seen on the MVS console:

```
```

If the message is not seen, a message explaining why FTP did not start up will appear in SYSLOG. Even if the above message is issued, it would be beneficial to inspect SYSLOG for warning messages issued during FTP initialization. EZY2700I displays the port FTP uses as the control port, the port it listens to for incoming connections from clients. In this example, FTP is listening to standard port 21.

The file syslog uses is defined in /etc/syslog.conf. The statement daemon.info /tmp/daemon.log directs SYSLOGD to save all the daemon messages in /tmp/daemon.log. Below is an example of output error messages.

```
EZYFT18I Using catalog '/usr/lib/nls/msg/C/ftpdmsg.cat' for FTP messages.
EZY2697I IBM FTP CS V1R10 21:04:56 on 04/17/08
EZY2640I Using dd:SYSFTPD=USER1.FTP.DATA for local site configuration parameters
EZY2636E SMFLOGN value not specified.
EZYFT46E Error in dd:SYSFTPD file: line 5 near column 8.
EZY2636E SMFREN value not specified.
EZYFT47I dd:SYSFTPD file, line 21: Ignoring keyword "EXTENSIONS REST_STREAM".
EZYFT47I dd:SYSFTPD file, line 29: Ignoring keyword "CTRLCONN".
EZYFT26I Using 7-bit conversion derived from 'ISO8859-1' and 'IBM-1047' for the control connection.
EZYFT33I Unable to open DDNAME 'SYSFTSX' for the data connection: EDC5129I No such file or directory.
EZYFT31I Using /'TPOUSER.STANDARD.TCPXLBIN' for FTP translation tables for the data connection.
EZYFT09I system information for VIC135: z/OS version 1 release 10 (2094)
EZY2700I Using port FTP control (21)
EZY2701I Inactivity time is 0
EZY2702I Server-FTP: Initialization completed at 21:05:57 on 04/17/08.

```

Verifying the FTP client

To verify that the FTP client works correctly, log onto TSO and issue the NETSTAT HOME command, or issue NETSTAT -h from the z/OS UNIX shell. These commands will show the interface addresses that are known to the system. Below is an example of the output from NETSTAT HOME:

```
MVS TCP/IP NETSTAT CS V1R9  TCPIP Name: TCPCS  14:22:17
Home address list:
  LinkName: OSADOD06L
Address: 9.67.115.13
  Flags: Primary
  LinkName: LSAMEH
Address: 9.1.1.1
  Flags: 
  LinkName: LOOPBACK
Address: 127.0.0.1
  Flags: 
  Address: fe80::9:6b00:671a:586
    Type: Link_Local
    Flags: Autoconfigured
  IntfName: V6SAMEH
    Address: 1::8
    Type: Global
    Flags: 
  IntfName: V6VIRT
    Address: 2::55
    Type: Global
    Flags: 
  IntfName: LOOPBACK6
```

Transferring files using FTP
To invoke the FTP client, use any address shown on the NETSTAT HOME address list. The first example below shows how you could log in to the FTP server at 9.67.115.13 using a batch job (the output of the batch job is not shown). The second example shows logging in to the FTP server at 9.67.113.37 from the TSO environment.

```
//FTPBATCH JOB FTPUSER,
// USER=USER1,PASSWORD=TCPSUP
//BATCH EXEC PGM=FTP
//OUTPUT DD SYSOUT=*  
//INPUT DD *
9.67.115.13
USER10 tcpusr
SITE FILE=SEQ
QUIT
/*

### Verifying FTP.DATA statements

You can verify many FTP.DATA statements by using the FTP client STAtus and LOCStat subcommands. The output from the STAtus and LOCStat subcommands depends on the client and server copy of FTP.DATA at each installation. The following sample shows the output of one system:

```
stat
EZA17011I >>> STAT
211-Server FTP talking to host ::ffff:10.1.2.3, port 1026
211-The control connection has transferred 115 bytes
211-There is no current data connection.
211-The next data connection will be actively opened
211-to host ::ffff:10.1.2.3, port 1026,

Verifying anonymous, banner, and other optional configuration information

Depending on your installation's choices for anonymous level, banner support chosen, exits, and so on, verification of support output will differ. To verify anonymous configuration at a particular installation, log in as anonymous and verify the behavior is as expected. For example, if EMAILADDRCHECK FAIL is specified in FTP.DATA, try to log in as anonymous using an incorrect email address as password. To verify banner support, login and verify the banners are displayed as expected. Below is a sample of FTP.DATA and FTP client output for one such installation.

```
; BANNER STUFF
EMAILADDRCHECK FAIL
BANNER USER1.TEST1
ADMINEMAILADDR FTPADMIN@MYSYSTEM.COM
; ANONYMOUS STUFF
ANONYMOUSLEVEL 3
STARTDIRECTORY HFS
```

```
ftp 9.67.113.63
IBM FTP CS V1R9 2006 349 01:35 UTC
FTP: using TCPCS

220-You have just read 'USER1.TEST1'
220-ADMINEMAILADDRESS is FTPADMIN@MYSYSTEM.COM
220 Connection will not timeout.
NAME (9.67.113.63:USER4):
anonymous no-email-pw
>>> USER anonymous
331 Send password please.
>>> PASS
530 PASS command failed.
Command:
```
As with the other optional configuration information, FTP-JES support can best be verified by logging in and confirming the FTP.DATA parameters chosen. To verify JES support, a simple batch job can be created if the JESINTERFACELEVEL is set to the security requirements of an installation. Below is the batch job and FTP client output for JESINTERFACELEVEL 2.

EZA1460I Command:
Chapter 13. The resolver

The resolver acts on behalf of programs as a client to perform the following functions:

- Access name servers to provide name-to-address or address-to-name resolution
- Allocate and read the TCPIP.DATA file
- Establish TCP/IP stack affinity for certain socket APIs
- Provide protocol and services information

To resolve the query for the requesting program, the resolver uses information that it obtains from the following sources:

- Available name servers
- The DNS response information that has been cached locally (when system-wide caching is enabled)
- Local definitions, such as /etc/hosts, /etc/ipnodes, HOSTS.SITEINFO, HOSTS.ADDRINFO, and ETC.IPNODES

The TCPIP.DATA statements control how (and if) the resolver uses name servers. For detailed information about TCPIP.DATA configuration statements, see z/OS Communications Server: IP Configuration Reference.

**Requirement:** The resolver address space must be started before any application or TCP/IP stack resolver calls can occur.

DNS overview

While TCP/IP applications refer to host computers by their IP addresses, it is easier to use host names. To enable the use of host names in a network, the Domain Name System (DNS) translates host names to IP addresses. Mapping must be consistent across the network to ensure interoperability. DNS provides the host name-to-IP address mapping through network server hosts called domain name servers. For detailed information about name servers, see “Domain name servers” on page 705. DNS can also provide other information about server hosts and networks such as the TCP/IP services available at a server host and the location of domain name servers in a network.

DNS organizes the hosts in a network into domains. A domain is a group of hosts that share the same name space in the domain hierarchy and are usually controlled within the same organization. Domains are arranged in a hierarchy. A special domain known as the root domain exists at the top of the hierarchy. The root domain servers store information about server hosts in the root domain and the name servers in the delegated, top-level domains, such as com (commercial), edu (education), and mil (military). The name servers in the top-level domain, in turn, store the names of name servers for their delegated domains, and so on.

The complete name of a host, also known as the fully qualified domain name (FQDN), is a series of labels separated by dots or periods. Each label represents an increasingly higher domain level within a network. The complete name of a host connected to one of the larger networks generally has more than one subdomain, as shown in the following examples:

```
host1.subdomain2a.subdomain2.rootdomain
user4720.eng.mit.edu
```

A domain name server requires the FQDN. The client resolver combines the host name with the domain name to create the FQDN before sending the name resolution request to the domain name server.

DNS also provides IP address-to-host name mapping. The DNS defines a special domain called in-addr.arpa to translate IPv4 addresses to host names, and the ip6.int and ip6.arpa domains for IPv6 address-to-host name translation. This kind of mapping is useful for producing output (host names) that is easy to read. An in-addr.arpa name is composed of the reverse octet order of an IP address

© Copyright IBM Corp. 2000, 2019
concatenated with the \texttt{in-addr.arpa} string. For example, a host named \texttt{Host1} has 9.67.43.100 as an IP address. The \texttt{in-addr.arpa} domain translates the Host1 IP address 9.67.43.100 to 100.43.67.9.in-addr.arpa.

A system administrator can name the host systems and domains in the local, private network with any name you want, but to link with name servers in a public network like the Internet, you need to determine which domain you want to be in (which parent domain) and then contact the registrar in that domain to register the names and IP addresses of your name servers. This ensures that queries from outside the domain being defined can be answered by this name server if need be.

\textbf{Note:} Contact the InterNetwork Information Center (InterNIC) for more information about Internet registration. You can contact InterNIC by pointing your web browser at \texttt{http://www.internic.net}.

\section*{Domain names}

The DNS uses a hierarchical naming convention for naming hosts. Each host name is composed of domain labels separated by periods. Local network administrators have the authority to name local domains within an intranet. Each label represents an increasingly higher domain level within an intranet. The fully qualified domain name of a host connected to one of the larger intranets generally has one or more subdomains:

- \texttt{host.subdomain.subdomain.rootdomain}
- \texttt{host.subdomain.rootdomain}

Domain names often reflect the hierarchy level used by network administrators to assign domain names. For example, the domain name \texttt{eng.mit.edu} is the fully qualified domain name, where \texttt{eng} is the host, \texttt{mit} is the subdomain, and \texttt{edu} is the highest level domain (root domain).

Figure 94 on page 704 is an example of the DNS used in the hierarchy naming structure across an intranet.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{hierarchical_naming_tree.png}
\caption{Hierarchical naming tree}
\end{figure}

You can refer to hosts in your domain by host name only; however, a name server requires a fully qualified domain name. The local resolver appends the domain name before sending the query to the Domain Name Server for address resolution.
Domain name servers

Domain name servers are designated network nodes that maintain a database of information about all nodes in some part of the domain name space, called a zone. A name server is said to be authoritative for its zone. A zone consists of the resources within a single domain (for example, commercial or .com) or subdomain (for example, raleigh.ibm.com). Typically, a zone is administered by a single organization or individual. The complete database is not kept by any one name server on a network. A name server is authoritative only within its zone of authority.

All host systems in a given zone share the same higher level domain name (for example, host1.raleigh.ibm.com, host2.raleigh.ibm.com, host3.raleigh.ibm.com, and so on). As system administrator, you create a zone of authority by listing all the host systems in your zone in the database file of the name server that is authoritative for the zone.

If a domain name server receives a query about a host for which it has information in its database or in its cache, it performs the name resolution and returns all the address records associated with the host to the client. Some hosts (for example, routers or gateways between two or more networks) might have more than one IP address.

Alternatively, the name server can query other name servers for information. This process is called iterative resolution. The local name server successively queries other name servers, each of which responds by referring the local name server to a remote name server that is closer to the name server authoritative for the target domain. Finally, the local name server queries the authoritative name server and gets an answer. If the information about a requested host name does not exist or if a name server does not know where to go for the information, it sends a negative response back to the client.

There are multiple name server modes in the DNS:

- Authoritative
  - Master (primary)
  - Secondary
- Caching-only servers
- Forwarders
- Stealth

A single server can perform multiple functions. For example, it can be a primary server and a secondary server for different zones. The purpose of having these different kinds of servers is to provide redundancy (in case of system failure), to distribute the workload among multiple servers, to speed up the name-resolution process, and to provide flexibility in network design. In addition to being an authoritative or caching-only server, a name server can be defined to contact only a specific set of name servers if queries cannot be resolved locally (through the use of forwarders).

The following subtopics discuss authoritative servers, caching-only servers, and forwarding.

Authoritative servers

An authoritative server is the authority for its zone. It queries and is queried by other name servers in the DNS. The data it receives in response from other name servers is cached. Authoritative servers are not authoritative for cached data.

There are two types of authoritative servers: master (primary) and secondary. Each zone must have only one master name server, and it should have at least one secondary name server for backup purposes to minimize dependency on a particular node. Calling a particular name server a master or secondary server is misleading. Any given name server can take on either or both roles, as defined by the conf file.

The zone data updates and maintenance are reflected in the master name server and the changes are then reflected in secondary name servers. Both master and secondary name servers are authoritative for a zone.

The zones of authority are arranged in a hierarchy based on the domain origin components. A special zone known as the root exists at the top of the domain name hierarchy in a network. The root zone contains a list of all the root servers. For example (see Figure 94 on page 704), in the Internet, the root name servers...
store information about nodes in the root domain, and information about the delegated domains, such as com (commercial), edu (education), and mil (military). The root name servers store the names of name servers for each of these domains, which in turn store the names of name servers for their delegated subdomains.

TCP/IP applications contact a name server whenever it is necessary to translate a domain name into an IP address, or when information is required about a domain. The name server performs the translation if it has the necessary information. If it does not have the necessary information, the name server can contact other name servers, which in turn can contact other name servers. This process is called a recursive query. Alternatively, a name server can return the address of another name server that might hold the requested information. This is called a referral response to a query. Name server implementations must support referrals, but are not required to perform recursive queries. See “Resolvers” on page 707 for more information about query responses.

**Master name servers**

A master name server maintains all the data for its zone. Static resources are kept in database files called domain data files. Master name servers can also receive zone updates dynamically.

**Secondary name servers**

A secondary name server acts as an alternate to the master name server if the master name server becomes unavailable or overloaded. The secondary name server receives zone data directly from the master name server in a process called zone transfer. Zone transfers occur only when data changes. Some name servers support zone change notification, which results in the zone transfer happening quickly after the data changes. Other name servers poll for changed data based on the refresh interval in the Start of Authority (SOA) resource record. For a description of the SOA resource record, see z/OS Communications Server: IP Configuration Reference. A secondary name server, like a master name server, is authoritative for a zone.

**Caching-only servers**

All name servers cache (store) the data they receive in response to a query. A caching-only server, however, is not authoritative for any domain. Responses derived from cached information are flagged in the response. When a caching-only server receives a query, it checks its cache for the requested information. If it does not have the information, it queries a local name server or a root name server, passes the information to the client, and caches the answer for future queries. The names and addresses of the root name servers are acquired from the servers listed in the hints file, the name and file path of which are specified in the name server's configuration file.

You can manually configure a name server to create a large cache of responses to queries that are frequently requested and reduce the number of queries made to master servers. The name server that you configure as a caching-only server stores data for a period of time determined by the time-to-live (ttl) value, and the cached information is lost if the name server is restarted.

**Tip:** As an alternative to manually configuring a caching-only server, you can use the cache that the resolver creates. The resolver cache is enabled by default and typically provides better system performance than using a caching-only name server that you have configured manually. For more information about using, configuring, and managing the resolver cache, see “Resolver caching” on page 724.

**Forwarders**

Normally, name servers answer queries from cached data or, if that does not succeed, they attempt to contact other name servers identified in their data files as authoritative for certain domains. However, name servers can also be configured to contact special servers called forwarders before contacting the name servers listed in their data files. If a forwarder cannot process the query and if the local name server is not a forward-only name server, the local name server contacts the name servers in its data files. A forward-only name server relies completely on its forwarders. It does not try to contact other servers to find out information if the forwarders do not give it an answer.
The forwarding function is useful for reducing the number of queries to servers on the Internet and for creating a large cache of information on forwarders. It is also a useful function for providing Internet access for local servers that, for one reason or another, do not have access themselves.

**Stealth server**

A *stealth server* is a server that answers authoritatively for a zone, but is not listed in that zone's NS records. Stealth servers can be used as a way to centralize distribution of a zone, without having to edit the zone on a remote name server. When the master file for a zone is on a stealth server in this way, it is often referred to as a *hidden primary* configuration. Stealth servers can also be a way to keep a local copy of a zone for rapid access to the zone's records, even if all official name servers for the zone are inaccessible.

**Resolvers**

Programs that query a name server are called *resolvers*. Because many TCP/IP applications need to query the name server, a set of routines is usually provided for application programmers to perform queries. On z/OS, these routines are available in the resolver provided by z/OS Communications Server.

z/OS Communications Server provides programs for interactively querying a name server:

- NSLOOKUP (TSO)
- *onslookup*/nslookup (z/OS UNIX)
- DIG (TSO)
- *dig* (z/OS UNIX)
- *host*

**Note:** The nsupdate program also makes queries to name servers as part of its operations.

For information on these programs, see *z/OS Communications Server: IP System Administrator's Commands*.

The onlookup command and the dig command use the resolver initialization facilities of the resolver provided by z/OS Communications Server, but use their own resolver for any additional resolver facilities needed.

**Resolver directives for nslookup**

The onlookup program uses the following resolver directives (TCPIP.DATA statements):

- domain/domainorigin
- search
- nameserver/nsinteraddr
- options debug/options ndots

**Resolver directives for dig**

The dig program uses the following resolver directives (TCPIP.DATA statements):

- domain/domainorigin
- search
- nameserver/nsinteraddr
- options ndots

**Query Packets**

Resolvers operate by sending query packets to a name server. A query packet contains the following fields:

- Domain name
- Query type
RFC 1035 defines the query types and query classes. The name server attempts to match the three fields of the query packet to its database. For flexibility, the following wildcard query types are defined:

**Type**

**Description**

**ANY**
- Indicates any record type for the domain name.

**AXFR**
- Indicates the query type used by secondary name servers to transfer all records in the zone. (The query class is set to IN when using the AXFR query type.)

**MAILB**
- Indicates any mailbox records for the domain name.

The name server can return the following query responses:

**Response**

**Description**

**Authoritative**
- Is returned from a primary or secondary name server. The name server contains all the domain data used to define the zone for the specified query.

**BADVERS**
- The name server received a request that contained a EDNS0 version that was not valid.

**Nonauthoritative**
- Is returned from a cache kept by a name server. The cache does not contain the domain data used to define the zone for the specified query.

**Format Error**
- The name server found an error in the query packet sent by the resolver.

**Name Error**
- No resource records of any type (including wildcards) exist for the domain name specified.

**NXDOMAIN (negative)**
- No records of the requested type were found for the domain name specified.

**Not-implemented**
- The name server does not support the type of query requested.

**NOTAUTH**
- The name server is not authoritative for the zone.

**NOTZONE**
- A dynamic update failed because the name to be updated is not contained within the given zone.

**NXRRSET**
- A dynamic update failed because the prerequisites were not satisfied. The Resource Record set existed when the prerequisite stated it should not.

**Referral**
- Contains the addresses of other name servers that might be able to answer the query. A referral response is returned when a recursive query is not supported, not requested, or cannot be answered because of network connectivity.

**Refused**
- The name server refuses to perform the specified operation. For example, some root name servers limit zone transfers to a set number of IP addresses.

**YXDOMAIN**
- DNAME mapping failed because the new name was too long.

**YXRRSET**
- A dynamic update failed because the prerequisites were not satisfied. The Resource Record set did not exist when the prerequisite stated it should.
Resource Records

Data from a name server is stored and distributed in a format known as a resource record. Each response from a name server can contain several resource records, which can contain a variety of information. The format of a response is defined in RFC 1035. It includes the following sections:

• A question section, echoing the query for which the response is returned.
• An answer section, containing resource records matching the query.
• An additional section, containing resource records that do not match the query, but might provide useful information for the client. For example, the response to a query for the host name of a name server for a specific zone includes the IP address of that name server in the additional section.
• An authority section, containing information specific to the type of response made to the query. If a referral is returned, this section contains the domain names of name servers that could provide an authoritative answer. If a negative response is returned indicating the name does not exist, this section contains a Start Of Authority (SOA) record defining the zone of authority of the responding name server.

Querying name servers

This topic describes how to use the nslookup command to query the name server. nslookup is an alias of nslookup in the z/OS UNIX environment.

Notes:

1. The z/OS UNIX nslookup command runs only from the z/OS shell. The nslookup command can query the name server from TSO or the z/OS shell. However, only the legacy TSO version of NSLOOKUP is available from TSO. See z/OS Communications Server: IP System Administrator's Commands for detailed information.

2. The host and dig commands are another way to query name servers from the z/OS shell. For information on the host and dig commands, see z/OS Communications Server: IP System Administrator's Commands.

nslookup command

The z/OS UNIX nslookup and TSO NSLOOKUP commands can be used to query the name server to perform the following tasks:

• Identifying the location of name servers
• Examining the contents of a name server database
• Establishing the accessibility of name servers

Note: sortlist is not supported by nslookup

The z/OS UNIX nslookup and TSO NSLOOKUP commands have two modes of operation: interactive mode and command mode. The address of the default name server comes from the resolver configuration data. In the sample data below, the default domain is raleigh.ibm.com, and the default name server is at 9.37.34.149. If that name server fails to respond, the one at 9.37.34.7 is used.

<table>
<thead>
<tr>
<th>domain</th>
<th>raleigh.ibm.com</th>
</tr>
</thead>
<tbody>
<tr>
<td>nameserver</td>
<td>9.37.34.149</td>
</tr>
<tr>
<td>nameserver</td>
<td>9.37.34.7</td>
</tr>
</tbody>
</table>

Entering the interactive mode

Interactive mode can be used to repetitively query one or more name servers for information about various hosts and domains, to display that information on the console, and, in some cases, to write response data to a file.

You can enter the interactive mode under the following conditions only:

• No arguments are supplied on command invocation or the -v option is specified; the default name server is used.
• The first argument is a hyphen, and the second argument is the host name or Internet address of a name server.

For a complete description of the z/OS UNIX and TSO nslookup interactive modes, see z/OS Communications Server: IP System Administrator's Commands.

**Entering the command line mode**

The command line mode displays or stores the output from the query supplied as part of the invocation string and then exits.

To enter the command line mode, provide a complete query with the z/OS UNIX nslookup command invocation string.

For a complete description of the z/OS UNIX and TSO nslookup command line modes, see z/OS Communications Server: IP System Administrator's Commands.

**nslookup configuration**

There are only two places to specify nslookup options: as command options, or from the resolver configuration data set. Only a few of the options may be set in the resolver configuration data set. The command options always have precedence over any option configured in the resolver configuration data set.

Only the following options can be specified in the resolver configuration data set for v9 nslookup:

• nameserver/nsinteraddr
• options ndots: n
• search
• domain/domainorigin

The z/OS UNIX nslookup command uses a private resolver that is different from the resolver used by other z/OS UNIX socket programs. The z/OS UNIX nslookup command has the following functional differences:

• z/OS UNIX nslookup does not use SiteTables (for example, /etc/hosts) for host name resolution.
• Only the built-in translation table is used for nslookup.

For a complete discussion of resolver configuration files, see Chapter 2, “IP configuration overview,” on page 11.

**Recommended reading**

The latest edition of DNS and BIND by Paul Albitz and Cricket Liu (O'Reilly & Associates, Inc.) gives a comprehensive description of DNS and BIND.

You can subscribe to a BIND users mailing list at http://lists.isc.org/mailman/listinfo.

DNS protocols are described in various Request for Comments (RFC) papers and Internet drafts. RFCs outline existing protocols, suggest new protocols, and establish standards for the Internet protocol suite. Internet drafts are proposals, techniques, and mechanisms that document Internet Engineering Task Force (IETF) work-in-progress.

For information about obtaining RFCs, see Appendix G, “Related protocol specifications,” on page 1381.

**Resolver API calls**

Application programs invoke resolver functions by using resolver API calls such as gethostbyname() and getaddrinfo(). The z/OS resolver supports a number of IBM APIs, although not all APIs support all possible resolver API calls. The z/OS resolver is invoked by the following resolver API calls:

• Application programs that use the gethostbyaddr() and gethostbyname() resolver calls from the following IBM APIs:
• Application programs that use the getaddrinfo(), getnameinfo(), and freeaddrinfo() resolver calls from the following IBM APIs:
  - z/OS XL C/C++ runtime library functions in z/OS XL C/C++ Runtime Library Reference
  - z/OS UNIX System Services (z/OS UNIX) callable services in z/OS UNIX System Services Programming: Assembler Callable Services Reference
  - z/OS Communications Server C/C++ API, z/OS Communications Server Callable and Macro API, z/OS Communications Server REXX API, and z/OS Communications Server PASCAL API in z/OS Communications Server: IP Sockets Application Programming Interface Guide and Reference

• Application programs that use the sethostent(), gethostent(), and endhostent() resolver calls from the following IBM APIs:
  - z/OS XL C/C++ runtime library functions in z/OS XL C/C++ Runtime Library Reference
  - z/OS Communications Server Callable and Macro API in z/OS Communications Server: IP Sockets Application Programming Interface Guide and Reference

The dig, nslookup, and nsupdate z/OS UNIX commands provide their own unique resolver services. When their resolver initializes, it uses the appropriate TCPIP.DATA information, including information from the global TCPIP.DATA file, if one is specified. For more information, see “The resolver and the global TCPIP.DATA file” on page 715.

Starting the resolver

Prior to starting the resolver, you must have a user ID defined for the resolver started procedure that includes an OMVS segment, so that the resolver can use z/OS UNIX services. For information about defining and assigning a user ID for started procedures, see z/OS Security Server RACF Security Administrator's Guide.

**Requirement:** If the resolver user ID does not have an OMVS segment and you are not using the automatic assignment of unique UNIX identities support to automatically generate OMVS segments, you must explicitly configure an OMVS segment for the resolver user ID. For more information about RACF and z/OS UNIX, see z/OS Security Server RACF Security Administrator's Guide.

**Guideline:** The HOME directory in the OMVS segment for the resolver user ID must be accessible when the resolver is started. Specify the root directory [HOME/] to avoid problems.

There are two ways that the resolver can be started:

• Use z/OS UNIX to start the resolver

The resolver is started when z/OS UNIX is initialized. This method of starting the resolver ensures that applications that require resolver services are not started before the resolver starts. If you use z/OS UNIX to start the resolver, you can use the default resolver settings (see “The default resolver settings” on page 712), or you can optionally create a start procedure and define the address space (see “Customizing the resolver” on page 712).

• Use automation tools to start the resolver

The resolver is started by issuing the MVS START operator command. You must customize the resolver to use this starting method; see “Customizing the resolver” on page 712 for more information. If you use this method of starting the resolver, then it is possible that an application that needs resolver services (such as INETD) is started before the resolver address space is initialized. In this case, you might need to remove the starting of INETD from the z/OS UNIX /etc/rc file and start INETD with automation after the resolver has initialized.
If you are using z/OS UNIX to start the resolver, then the following actions occur when z/OS UNIX is initialized:

- **z/OS UNIX uses SUB=MSTR to start the resolver (the resolver does not require JES); for information about SUB=MSTR, see z/OS MVS JCL Reference**

- **z/OS UNIX issues an informational message that contains the name of the procedure that it is starting:**
  
  
  BPXF224I THE RESOLVER_PROC, procname, IS BEING STARTED

  **Rule:** If the RESOLVER_PROC statement is not present or is specified with the procedure name DEFAULT, the procname value is RESOLVER, even though a start procedure was not used. For more information about the RESOLVER_PROC statement, see z/OS MVS Initialization and Tuning Reference.

- **If the start procedure is not found or if it contains a JCL error, then error messages for the z/OS START command are issued and the resolver address space does not initialize.**

- **If the resolver address space cannot be started, z/OS UNIX initialization continues.**

The default resolver settings

You do not have to perform any customization steps to use the resolver. The default resolver starts automatically when z/OS UNIX is initialized; you cannot use automation tools to start the resolver unless you customize it. z/OS UNIX starts a resolver address space, which uses the assigned name RESOLVER, using the system default procedure IEESYSAS. The resolver uses the applicable native MVS or z/OS UNIX search order to find TCPIP.DATA statements, without a GLOBALTCPIPDATA or a DEFAULTTCPIPDATA specification.

The following resolver functions are active by default:

- System-wide caching, which uses the default maximum cache size, the default maximum time-to-live (TTL) value, and the default setting for the cache reordering function. See “Resolver caching” on page 724.

- Network operator notification of unresponsive Domain Name System (DNS) servers, using the default threshold setting. See “Monitoring the responsiveness of Domain Name System name servers” on page 735.

The Extension Mechanisms for DNS (EDNS0) standards function is always active. For more information, see “Extension Mechanisms for DNS standards and the resolver” on page 743.

Customizing the resolver

You can customize resolver functions, or enable or disable certain resolver functions, by using resolver configuration statements in a resolver setup file. For example, you can control which resolver statements are used by all applications or TCP/IP stacks for name resolution by specifying the GLOBALTCPIPDATA statement (see “The resolver setup file” on page 712 for more information about the statements that are supported by the resolver setup file). If you want to customize resolver functions, you must create a resolver setup file and define the resolver address space.

The resolver setup file

The resolver setup file is an optional file (either an MVS data set or a z/OS UNIX file) that contains resolver configuration statements that you can use to customize resolver functions.

If the resolver setup file is an MVS data set, the file must have the following characteristics:

- Use sequential (PS) or partitioned (PO) organization
- Use fixed (F) or fixed block (FB) format
- Contain a logical record length (LRECL) that is 80 - 256 bytes in length
- Contain any valid blocksize (BLKSIZE) for a fixed block
• If you think you will need to modify the setup file, use a member of an MVS partitioned data set.

If the resolver setup file is a z/OS UNIX file, the file can be located in any directory. The maximum line length that is supported is 256 characters. If a line is longer than 256 characters, then the line is truncated to 256 characters before it is processed.

If you do not use a resolver setup file, the resolver uses the applicable native MVS or z/OS UNIX search order without any additional information and performs the following functions using the default settings:

• Enables system-wide caching (using the default maximum cache size and the default time-to-live [TTL] value)
• Monitors Domain Name System (DNS) name server responsiveness (using the default threshold setting)

The following statements are supported by the resolver setup file:

• Comments (; or #)
• CACHE
  Enables system-wide caching of DNS queries that have been resolved. System-wide caching is enabled by default, but you can explicitly enable it using this statement. For more information about caching, see “Resolver caching” on page 724.
• CACHEORDER
  Enables system-wide reordering of a cached list of IP addresses in response to resolver API queries for the associated host name. If you do not specify this statement, system-wide reordering of a cached list is disabled by default.
• CACHESIZE
  Defines the amount of storage that can be allocated by the resolver to manage cached records.
• COMMONSEARCH
  Indicates that the same search order for local host files is used for both IPv4 and IPv6 name queries.
• DEFAULTIPNODES
  Identifies the default local host file.
• DEFAULTTCPIPDATA
  Identifies a default TCPIP.DATA file. The file that is specified by the DEFAULTTCPIPDATA statement becomes the last file that is searched by the resolver for resolver configuration information. If you do not specify the DEFAULTTCPIPDATA statement, the default file is TCPIP.TCPIP.DATA. For more information, see “The resolver and the global TCPIP.DATA file” on page 715.
• GLOBALIPNODES
  Identifies a local host file that contains hard-coded IP addresses and host names that can be used globally.
• GLOBALTCPIPDATA
  Identifies the file that is the first file that is searched by the resolver for resolver configuration information. Parameters that you specify in the file that is identified by the GLOBALTCPIPDATA statement become the global settings for the entire MVS image and for all TCP/IP stacks. For more information, see “The resolver and the global TCPIP.DATA file” on page 715.

**Restriction**: You must code the GLOBALTCPIPDATA statement if the AUTOQUIESCE operand is coded on the UNRESPONSIVETHRESHOLD statement. If you cannot ensure that all DNS IP addresses are accessible from all your TCP/IP stacks, you should not use a global TCPIP.DATA file, and you should not code AUTOQUIESCE on the UNRESPONSIVETHRESHOLD setup statement in your resolver setup file. For more information about the UNRESPONSIVETHRESHOLD statement, see z/OS Communications Server: IP Configuration Reference.

• MAXTTL
  Defines the amount of time that the resolver can use resource information that it receives from a name server.
• NOCACHE
  Disables system-wide caching of DNS response data. If you do not specify this statement, system-wide caching is enabled by default.

• NOCACHEREORDER
  Disables system-wide reordering of a cached list of IP addresses in response to resolver API queries for the associated host name. System-wide reordering of a cached list of IP addresses is disabled by default, but you can explicitly disable it by using this statement.

• NOCOMMONSEARCH
  Indicates that a different search order for local host files is used for IPv4 and IPv6 name queries.

• UNRESPONSIVETHRESHOLD
  Identifies the threshold value that determines when the resolver declares a DNS name server to be unresponsive. If the percentage of query failures to a name server during a fixed interval is greater than or equal to this threshold value, the resolver considers the name server to be unresponsive. The resolver might stop sending DNS queries that are generated by an application to unresponsive name servers, depending on the values that are coded on this statement. For more information, see “Monitoring the responsiveness of Domain Name System name servers” on page 735.

**Restriction:** You must code the GLOBALTCPIPDATA statement if the AUTOQUIESCE operand is coded on the UNRESPONSIVETHRESHOLD statement. If you cannot ensure that all DNS IP addresses are accessible from all your TCPIP stacks, you should not use a global TCPIP.DATA file, and you should not code AUTOQUIESCE on the UNRESPONSIVETHRESHOLD setup statement in your resolver setup file. For more information about the UNRESPONSIVETHRESHOLD statement, see z/OS Communications Server: IP Configuration Reference.

For more information about resolver setup statements, see z/OS Communications Server: IP Configuration Reference.

**Resolver processing of the setup file when the resolver is started**

During resolver address space initialization, the resolver parses the entire resolver setup file using the following rules:

• When a setup statement has a syntax error, the resolver generates a warning message to the console and the setup statement is skipped.

• When the resolver does not recognize a setup statement, the resolver generates a warning message to the console and the setup statement is skipped.

• When the resolver parses multiple instances of the same setup statement that have no syntax errors, the resolver uses the setting on the last instance that is parsed.

• When the resolver completes parsing of the resolver setup file and did not parse any instances of a resolver setup statement that are syntactically correct, the resolver takes the default value for that setup statement

• When a resolver setup statement (for instance, GLOBALTCPIPDATA) specifies an MVS data set name or a z/OS UNIX file name that the resolver cannot open or access, the resolver considers that to be a syntax error.

• When there are multiple instances of a setup statement that have no syntax errors and that specify an MVS data set name or z/OS UNIX file name, the resolver attempts to open or access the data set or file specified on only the last instance that is parsed. If the resolver cannot open or access this data set or file, the resolver proceeds as if this setup statement had not been specified.

• When the resolver cannot open the resolver setup file, the resolver uses all the default settings for the configuration.

• When the resolver setup file is the wrong format, the resolver uses all the default settings for the configuration.
• If the resolver generates any warning messages due to syntax errors or unrecognized statements during resolver address space initialization, the resolver issues message EZD2038I at the conclusion of resolver address space initialization.

• If the resolver does not generate any warning messages during resolver address space initialization, the resolver issues message EZZ9291I when the address space is initialized.

Results:

• Consider a resolver setup file that contains the following statements:

```
CACHE
NOCACHE
CACH
```

The resolver issues a warning message for the line specifying the value CACH and ignores the value. Because NOCACHE was parsed after the valid statement CACHE, the resolver uses the NOCACHE setup statement and caching is disabled for this system.

• Consider a resolver setup file that contains the following statements:

```
GLOBALTCPIPDATA(/etc/tcpip.data)
GLOBALTCPIPDATA(/etc/newer.tcpip.data)
DEFAULTTCPIPDATA(/etc/default.tcpip.data)
```

Each of these statements is syntactically correct, so the resolver uses the value coded on the last GLOBALTCPIPDATA statement as the name of the global TCPIP.DATA file. The resolver attempts to access the files /etc/newer.tcpip.data and /etc/default.tcpip.data. If the file /etc/newer.tcpip.data does not exist, the resolver generates a warning message and proceeds as if no global file were specified; the resolver does not attempt to use /etc/tcpip.data as the global TCPIP.DATA file. If /etc/default.tcpip.data does not exist, the resolver generates a warning message and proceeds as if no default file were specified.

**The resolver and the global TCPIP.DATA file**

The optional GLOBALTCPIPDATA statement identifies a global TCPIP.DATA file, in which you can specify global settings. If you specify a global TCPIP.DATA file, you can control which resolver statements are used for name resolution and you do not need to merge resolver statements from multiple files. TCPIP.DATA statements in this file are the first that are searched, regardless of which socket API library you are using.

If you use a global TCPIP.DATA file, you can specify the following resolver statements, or you can use the default values. These statements are required by the resolver to process queries.

• DomainOrigin or Domain
• NSInterAddr or NameServer
• NSPortAddr
• ResolveVia
• ResolverTimeOut
• ResolverUDPRetries
• Search
• SortList

If you specify any of these statements in the global TCPIP.DATA file, those settings become the global settings for this MVS image and for all users of resolver services, across the entire system. If you do not specify one of these statements in the global TCPIP.DATA file, the resolver uses the default values. The search continues beyond the global TCPIP.DATA file, but any of these resolver statements that are specified in files that are located lower in the search order are ignored.

If you do not identify a global TCPIP.DATA file, then the resolver uses the regular search order until it finds a local TCPIP.DATA file.
Restriction: You must code the GLOBALTCPIPDATA statement if you want to use the autonomic quiescing of unresponsive name servers function. For more information, see "Monitoring the responsiveness of Domain Name System name servers" on page 735.

If you do not specify one of these statements in this local TCPIP.DATA file, the resolver uses the default values. The setting that the resolver uses applies only to this application, not to all users of resolver services. In any case, the search order depends on whether the native MVS or z/OS UNIX application environment is in use. The search order for the local hosts table (HOSTS.xxxxINFO, ETC.IPNODES, /etc/hosts, or /etc/ipnodes) remains the same.

You can specify other statements in the global TCPIP.DATA file (for information about configuration statements in TCPIP.DATA, see z/OS Communications Server: IP Configuration Reference). There are some statements, like Trace Resolver, for which you likely do not want a global setting. If you do not specify one or more of these other statements in the global file, the resolver uses the regular search order until it finds a local TCPIP.DATA file. If you do not specify these other statements in the local TCPIP.DATA file, the resolver uses the default values. You can implement these global settings gradually, in case there are private TCPIP.DATA files that are in use on your system about which you are unaware.

You can identify a global TCPIP.DATA file in a CINET (common INET) environment. You specify in the global TCPIP.DATA file all the resolver statements for which you want to set a global value, and the resolver conducts its searches in the same way as in a non-CINET environment. However, if you do use a global TCPIP.DATA file in a CINET environment, all the resolver statements must be usable by all stacks. For example, the IP addresses that are specified by the NameServer statement must be accessible from all stacks. If the IP addresses are not accessible, then you should not use a global TCPIP.DATA file; use multiple TCPIP.DATA data sets instead. If you use multiple TCPIP.DATA data sets, you should not code the AUTOQUIESCE operand on the UNRESPONSIVETHRESHOLD statement in the resolver setup file.

You can use the DEFAULTTCPIPDATA setup statement to specify a TCPIP.DATA file as the last TCPIP.DATA file that is searched, instead of TCPIP.TCPIP.DATA. You can specify any file as the default file.

Steps for creating a resolver setup file
The SETUP DD statement in the start procedure for the resolver points to the resolver setup file. The setup file can be an MVS data set or a z/OS UNIX file.

Procedure
Perform the following steps to create a resolver setup file:
1. Use an MVS data set or a z/OS UNIX file for your setup file, depending on your requirements.
2. Customize the search order that the resolver uses to resolve queries by specifying one or more of the following statements:
   - Specify the GLOBALTCPIPDATA statement to identify the global TCPIP.DATA file that becomes the first file that is searched. Parameters that you specify in this file become the global settings for the entire MVS image and for all users of resolver services, across the entire system.
     
     Restriction: You must code the GLOBALTCPIPDATA statement if the AUTOQUIESCE operand is coded on the UNRESPONSIVETHRESHOLD statement. If you cannot ensure that all DNS IP addresses are accessible from all your TCPIP stacks, you should not use a global TCPIP.DATA file, and you should not code AUTOQUIESCE on the UNRESPONSIVETHRESHOLD setup statement in your resolver setup file. For more information about the UNRESPONSIVETHRESHOLD statement, see z/OS Communications Server: IP Configuration Reference.
   - Specify the DEFAULTTCPIPDATA statement to identify a default TCPIP.DATA file. The file specified by the DEFAULTTCPIPDATA statement becomes the last file that can be searched. If you do not specify the DEFAULTTCPIPDATA statement, the default file is TCPIP.TCPIP.DATA.
   - Specify either the GLOBALIPNODES statement or the DEFAULTIPNODES statement to identify a local host file. The GLOBALIPNODES statement identifies a local host file that contains hard-coded IP addresses and host names that can be used globally. The DEFAULTIPNODES statement identifies the default local host file.
Result: You can specify both the GLOBALIPNODES statement and the DEFAULTIPNODES statement, but the resolver search order for local host files ensures that only the global IPNODES file is used. For more information, see “Search orders used in the z/OS UNIX environment” on page 751 and “Search orders used in the native MVS environment” on page 755.

• Specify the COMMONSEARCH statement or the NOCOMMONSEARCH statement. The COMMONSEARCH statement indicates that the same search order for local host files is used for both IPv4 and IPv6 name queries, and for MVS and UNIX searches. The NOCOMMONSEARCH statement indicates that different search orders for local host files are used for IPv4 and IPv6 name queries, and for MVS and UNIX searches. For more information, see “Search orders used in the z/OS UNIX environment” on page 751 and “Search orders used in the native MVS environment” on page 755.

• Specify the CACHE statement or the NOCACHE statement. The CACHE statement enables system-wide caching of Domain Name System (DNS) queries that have been resolved. System-wide caching is enabled by default, but you can explicitly enable it using this statement. See “Resolver caching” on page 724 for more information about caching. The NOCACHE statement indicates that you do not want to cache DNS response data.

  – If you are using system-wide caching, specify the CACHESIZE statement to define the amount of storage that can be allocated by the resolver to manage cached records. If you specify this statement and the NOCACHE statement, the CACHESIZE statement is ignored.
  – If you are using system-wide caching, specify the MAXTTL statement to define the amount of time that the resolver can use resource information that it receives from a name server. If you specify this statement and the NOCACHE statement, the MAXTTL statement is ignored.
  – If you are using system-wide caching, you can enable the resolver to reorder the cached list of IP addresses when the resolver responds to a host name resolution request.

    - To enable reordering of a list of cached IP addresses in a round-robin manner, specify the CACHEREORDER statement.
    - To disable reordering of a list of cached IP addresses, specify the NOCACHEREORDER statement.

    If you specify the NOCACHE statement, the CACHEREORDER and NOCACHEREORDER statements are ignored.

• Specify the UNRESPONSIVETHRESHOLD statement to define the threshold value that is used by the resolver to declare that a DNS name server is unresponsive. The monitoring of unresponsive name servers is enabled by default, but you can explicitly enable it using the UNRESPONSIVETHRESHOLD statement. In addition to specifying the threshold value, use the UNRESPONSIVETHRESHOLD statement to indicate how you want the resolver to react when an unresponsive name server is detected:

  – Specify only the threshold value on the UNRESPONSIVETHRESHOLD statement to indicate that the resolver should only alert the operator that a name server is unresponsive. The resolver will continue to send DNS queries that are generated by an application to the name server.
  – Specify the AUTOQUIESCE operand on the UNRESPONSIVETHRESHOLD statement to indicate that the resolver should stop sending DNS queries that are generated by an application to unresponsive name servers.

Restriction: You must code the GLOBALTCPIPDATA statement if the AUTOQUIESCE operand is coded on the UNRESPONSIVETHRESHOLD statement. If you cannot ensure that all DNS IP addresses are accessible from all your TCPIP stacks, you should not use a global TCPIPDATA file, and you should not code AUTOQUIESCE on the UNRESPONSIVETHRESHOLD setup statement in your resolver setup file. For more information about the UNRESPONSIVETHRESHOLD statement, see z/OS Communications Server: IP Configuration Reference.

If you do not want the resolver to maintain awareness of unresponsive name servers, you can use the UNRESPONSIVETHRESHOLD statement to disable resolver monitoring of name server responsiveness to DNS queries.
The following example setup file is located in SEZAINST as member EZBRECNF (alias RESSETUP):

```plaintext
; IBM Communications Server for z/OS
; SMP/E distribution name: EZBRECNF

5694-A01 Copyright IBM Corp. 2002, 2011, Licensed Materials - Property of IBM

Function: Sample Resolver setup file

The following statement defines the final search location for TCPIP.DATA statements. It will replace TCPIP.TCPIP.DATA
It may be an MVS data set or HFS file.
DEFAULTTCPIPDATA('TCPIP.TCPIP.DATA')

# The following statement defines the first search location for TCPIP.DATA statements. It may be an MVS data set or HFS file.
# Update with the correct data set or HFS file name
GLOBALTCPIPDATA('TCPCS.SYS.TCPPARMS(GLOBAL)')
GLOBALTCPIPDATA('/etc/tcpipglobal.data')

# The following statement defines the first search location for IPNODES statements. It may be an MVS data set or HFS file.
# Update with the correct data set or HFS file name
GLOBALIPNODES('TCPCS.SYS.TCPPARMS(IPNODES)')
GLOBALIPNODES('TCPCS.ETC.IPNODES')
GLOBALIPNODES('/etc/ipnodes')

# The following statement defines the final search location for IPNODES statements. It may be an MVS data set or HFS file.
# Update with the correct data set or HFS file name
DEFAULTIPNODES('TCPCS.SYS.TCPPARMS(IPNODES)')
DEFAULTIPNODES('TCPCS.ETC.IPNODES')
DEFAULTIPNODES('/etc/ipnodes')

# The following statement defines if the common search order should be used or not.

```
# The following statement defines the maximum amount of time that
# the resolver can use resource information that was cached as
# a result of a query to a name server.
# MAXTTL(2147483647)

# The following statement defines the threshold value for declaring
# a name server as unresponsive.  The AUTOQUIESCE option defines
# whether resolver temporarily stops using unresponsive name servers.
# You must code the GLOBALTCPIPDATA statement when you specify the
# AUTOQUIESCE option on the UNRESPONSIVETHRESHOLD statement.
; UNRESPONSIVETHRESHOLD(25)
; UNRESPONSIVETHRESHOLD(100, AUTOQUIESCE)

The resolver address space

The resolver address space must be started before any application or TCP/IP stack resolver calls can occur. When the address space starts, it reads an optional resolver setup data set that is pointed to by the SETUP DD card in the resolver JCL procedure. To use the functions that are provided by the GLOBALTCPIPDATA statement and other statements, you must define a resolver address space. You use a BPXPRMxx statement, RESOLVER_PROC, to specify the procedure name, if any, to be used by z/OS UNIX to start the resolver address space. If the RESOLVER_PROC statement is not in the BPXPRMxx parmlib member or is specified with the procedure name DEFAULT, z/OS UNIX starts a resolver address space that has the assigned name RESOLVER.

Steps for defining the resolver address space

You must define the resolver address space to use the functions provided by the GLOBALTCPIPDATA statement and other statements.

Before you begin

You must have already created a resolver setup file, if you are using one.

Procedure

Perform the following steps to define the resolver address space:
1. Create a start procedure.
   The start procedure has the following requirements:
   • The procedure must not contain any DD cards that specify SYSOUT=*.
   • The procedure must be in a data set that is specified by the IEFPDSI DD card specification of the MSTJCLxx PARMLIB member. If the procedure is not in this location, the resolver will not start. For information about MSTJCL, see z/OS MVS Initialization and Tuning Reference.

   To process its definitions, the resolver might need to allocate data sets or files. For those definitions, such as GLOBALTCPIPDATA, DEFAULTTCPIPDATA, /etc/hosts, HOSTS.SITEINFO, and HOSTS.ADDRINFO, allocation messages appear in the JES joblog. For long-running applications that heavily use resolver services, such as IBM Tivoli NetView for z/OS, consider using a started job that specifies MSGLEVEL=(1,0) to eliminate all allocation messages. This specification could also eliminate allocation messages that might be useful for problem analysis. For information about started jobs and the MSGLEVEL parameter, see z/OS MVS JCL Reference.

   See the example resolver startup procedure.

2. In the SETUP DD JCL statement, specify the location of the setup file.
3. Grant read access (using RACF or other security program) to the following files for the user ID that is assigned to the resolver address space:
   • SYS1.PARMLIB
   • The resolver setup file
   • The file specified by the GLOBALTCPIPDATA statement, if you are using one
• The file specified by the DEFAULTTCPIPDATA statement, if you are using one
• The file specified by the GLOBALIPNODES statement, if you are using one
• The file specified by the DEFAULTIPNODES statement, if you are using one

4. If you are using any of the following files, grant read access to the files for the user IDs or jobs that are using TCP/IP facilities:
   • The file specified by the GLOBALTCPIPDATA statement
   • The file specified by the DEFAULTTCPIPDATA statement
   • The file specified by the GLOBALIPNODES statement
   • The file specified by the DEFAULTIPNODES statement
   • /etc/hosts
   • /etc/ipnodes
   • /etc/services
   • HOSTS.SITEINFO
   • HOSTS.ADDRINFO
   • ETC.IPNODES
   If you do not specify the correct permission bit settings for a file to allow that file to be read, error message IEC141I 013-C0 is issued. Other error messages might also be issued that indicate that a file cannot be read.

5. (Optional) If you want z/OS UNIX to start the resolver (rather than using automation to start the resolver with the MVS START operator command), specify the resolver start procedure name as the procname value in the RESOLVER_PROC(procname) statement of the BPXPRMxx parmlib member. See “Starting the resolver” on page 711 for information about starting the resolver.
   **Guideline:** The default procedure name is RESOLVER. If you want to specify a procedure that uses the name RESOLVER, then specify RESOLVER for the procname value.
   If you do not specify the RESOLVER_PROC statement or if you specify DEFAULT, then z/OS UNIX starts a resolver address space using the system default procedure IEEYSAS with the assigned name RESOLVER. If you do not want to use z/OS UNIX to start the resolver, you must use the MVS START command to start the resolver address space.

6. If you use automation to start the resolver, consider looking for message EZD2038I and taking corrective action based on the warning messages that are generated by the resolver.
   The resolver issues messages during resolver address space initialization identifying the errors that exist in the resolver setup file. If the resolver issues message EZD2038I at the end of resolver address space initialization, there were setup statements with syntax errors or setup statements that were not recognized in the setup file. The errors might include errors accessing or opening one or more of the files specified on resolver setup statements, such as the GLOBALTCPIPDATA statement.

**Results**

The following example resolver start procedure is located in SEZAINST as member EZBREPRC (alias RESOPROC).

```bash
//RESOLVER PROC PARMS='CTRACE(CТИRES00)'
//** IBM Communications Server for z/OS
//** SMP/E distribution name: EZBREPRC
//** Licensed Materials - Property of IBM
//** Function: Start Resolver
//** /EZBREINI EXEC PGM=EZBREINI,REGION=0M,TIME=1440,PARM=6PARMS
//** When the Resolver is started by UNIX System Services it is
```
Managing the resolver address space

The resolver start procedure name is used with the following MVS system commands to manage the resolver address space:

- Start (S)
- Stop (P)

You should stop and restart the resolver only when a new level of the resolver code has been installed.

- Force
- Modify (F)

Use the MODIFY command to dynamically change resolver setup statements, to update the use of TCPIP.DATA statements, or to update the use of local host and services tables.

You can also use the MODIFY command to delete the information that the resolver has acquired about name server capabilities, and to restart the monitoring of unresponsive DNS name servers function after the resolver has stopped monitoring because of a system error.

You can use the MODIFY FLUSH command to delete all the resolver cache data.

Guideline: If you use the MODIFY command to dynamically change resolver setup statements and the resolver detects unrecognized setup statements or setup statements with syntax errors in the setup file specified on the MODIFY command, the resolver does not process the MODIFY command.

See z/OS Communications Server: IP System Administrator's Commands for more information about these commands.

You can use the following MVS system commands to control and display the status of the resolver CTRACE facilities:

- Trace CT
- Display Trace

See z/OS Communications Server: IP Diagnosis Guide for information about using CTRACE.

Steps for manually restarting the resolver

If the resolver is stopped for any reason, manually restart the resolver.

Before you begin

When you start the resolver, specify REUSASID=YES on the START command to ensure that a reusable ASID is used. If the resolver address space is stopped enough times and you do not specify REUSASID=YES, when you restart the resolver, all available ASIDs might be exhausted, which prevents
the creation of a new address space on the system. If a new address space is not created on the system, an IPL is required. For more information about tuning parameters for the maximum number of ASIDs on a system, see the MAXUSER parameter in z/OS MVS Initialization and Tuning Reference.

Procedure
Perform one of the following steps to restart the resolver:

- If you have not customized the resolver (you have not created a start procedure and you have not defined the address space), then issue the following system operator command:

  ```
  START IEESYSAS.RESOLVER,PROG=EZBREINI,SUB=MSTR,REUSASID=YES
  ```

- If you have customized the resolver, issue one of the following system operator commands, where `procname` is the name of the PROCLIB member that you created:

  ```
  START procname,REUSASID=YES
  START procname,SUB=MSTR,REUSASID=YES
  ```

Steps for applying an interim fix to the resolver

To apply IBM-supplied interim fixes to the resolver, you do not need to stop and restart the TCPIP started task or any application programs.

Before you begin
For the short duration of time that the resolver is not running, all resolver requests will fail.

Procedure
Perform the following steps to apply an interim fix to the resolver:

1. Use SMP/E to apply the interim fix.
2. If LLA (library lookaside) is running, refresh it by issuing the following operator command:

   ```
   MODIFY LLA,REFRESH
   ```

3. Stop the resolver by performing one of the following steps:
   - If you have not customized the resolver (you have not created a start procedure), issue the following system operator command:

     ```
     STOP RESOLVER
     ```
   - If you have customized the resolver, issue the following system operator command, where `procname` is the name of the PROCLIB member that you created:

     ```
     STOP procname
     ```

4. Restart the resolver by performing one of the following steps:
   - If you have not customized the resolver (you have not created a start procedure), issue the following system operator command:

     ```
     START IEESYSAS.RESOLVER,PROG=EZBREINI,SUB=MSTR,REUSASID=YES
     ```
   - If you have customized the resolver, issue one of the following system operator commands, where `procname` is the name of the PROCLIB member that you created:

     ```
     START procname,REUSASID=YES
     START procname,SUB=MSTR,REUSASID=YES
     ```

Rule: When you manually stop and then restart the resolver, specify REUSASID=YES on the START command to ensure that a reusable ASID is used. If the resolver address space is stopped enough
times and you do not specify REUSASID=YES then when you restart the resolver, all available ASIDs might be exhausted, which would prevent the creation of a new address space on the system. If a new address space is not created on the system, an IPL is required. For more information on tuning parameters for the maximum number of ASIDs on a system, see the MAXUSER parameter in z/OS MVS Initialization and Tuning Reference.

IPv6 name servers and the resolver

The z/OS resolver can communicate to a Domain Name System (DNS) name server using either IPv4 or IPv6 communications. When the resolver is operating on an IPv6-capable system, the resolver opens either an IPv6 socket or an IPv4 socket to connect to the target DNS name server, depending on the IP addresses of the potential target name servers. If both IPv6 and IPv4 addresses are specified as IP addresses for the target name servers, the resolver opens an IPv6 socket and relies on TCP/IP stack processing of IPv4-mapped IPv6 addresses to provide the appropriate communication with the name server. When the resolver is operating on an IPv4-only system, any IPv6 address specified as a target name server is ignored.

The list of name servers to be searched, as defined using the NSINTERADDR or NAMESERVER configuration statements in the TCPIP.DATA file, is stored in the res_state control block structure. Depending on the API used, applications can obtain the res_state control block, and can examine or even modify the contents of the res_state list of name servers (nsaddr_list). The nsaddr_list structure is not designed to accommodate IPv6 addresses, and changing the structure to accommodate IPv6 addresses would adversely affect existing applications. Therefore, resolver does not save IPv6 addresses into the nsaddr_list array, and returns only the IPv4 addresses coded on the NSINTERADDR or NAMESERVER configuration statements. If only IPv6 addresses are specified for name server addresses, the nsaddr_list array returns an empty list in res_state. If your application examines the contents of the res_state control block, in particular the nsaddr_list information, and requires that at least one name server IP address be present in the list, you need to specify at least one IPv4 address on a NSINTERADDR or NAMESERVER statement in the TCPIP.DATA file used by the application. Although nsaddr_list does not reflect the IPv6 addresses specified in the TCPIP.DATA file, resolver maintains the full list internally and uses the entire list for searching and caching purposes, unless the application modifies nsaddr_list for its own purposes.

The following z/OS function do not use the resolver's ability to communicate to a name server using IPv6:

- The TSO DIG and TSO NSLOOKUP commands do not support specification of an IPv6 address as the target server IP address, either explicitly on the command or as an entry in the TCPIP.DATA file.

If you choose to use IPv6 name servers, ensure that the setting for the MAXSOCKETS parameter on the BPXPRMxx AF_INET6 NETWORK statement is sufficiently large enough to include the number of IPv6 sockets being opened by resolver. Use the following rough calculations to determine whether the MAXSOCKETS value is large enough:

1. Determine how many concurrent resolver calls typically occur on your system. Each resolver call that involves communication with a DNS name server opens 1 or 2 sockets depending on the actual resolver API being used.
2. Determine the largest number of IPv6 sockets you have open on your system at any one point in time.
3. Add (number of concurrent resolver calls * 2) and the largest number of IPv6 sockets together. Compare this number against the setting of MAXSOCKETS on the appropriate BPXPRMxx AF_INET6 NETWORK statement.
   
   - If the MAXSOCKETS setting is the larger value, then the setting is acceptable.
   - If the MAXSOCKETS setting is the lesser value, update the MAXSOCKETS setting to the larger number.
Resolver functions

To use the resolver functions efficiently in your environment, you need to be familiar with the following resolver functions that are active, by default, when the resolver is started:

- Resolver caching
- Monitoring responsiveness of Domain Name System name servers
- Extension Mechanisms for DNS standards

Resolver caching

In the context of resolvers, *caching* is defined as saving and storing information from resolved DNS queries so that the information can be reused. A *cache* is the area of memory where the information is kept. The primary advantage of caching is the improved performance that is obtained by the elimination of repetitive queries to the name servers.

For example, in the configuration shown in Figure 95 on page 724, a local caching-only DNS name server is defined to provide some level of resource caching.

![Diagram of caching-only name server example](image)

*Figure 95. Local caching-only name server example*

In the caching-only name server model depicted in Figure 95 on page 724, when a request for host.raleigh.ibm.com is received, the resolver contacts the local name server (see arrow 1). The local name server then must perform standard name-server processing to locate the resource, which might include contacting one or more name servers (see arrows 2 through 9). When the name server that can provide an authoritative response for the queried host name is found and the response is returned to the local name server, the local name server caches the information and forwards it back to the resolver (arrow 10).

However, in the caching-only name server model depicted in Figure 95 on page 724, subsequent requests to the resolver for information about host.raleigh.ibm.com still require that a DNS query be created and forwarded to the local name server to obtain the cached results. This DNS query can be eliminated if the resolver itself caches the information, as shown in Figure 96 on page 725.
In the resolver caching model, when the initial query of the resolver cache (arrow 1) does not return any host name information, the DNS query is sent to the network name server (arrow 2), which might or might not already have information cached about host.raleigh.ibm.com. When the response is received (arrow 3), the information is cached by the resolver (arrow 4), and subsequent requests for host.raleigh.ibm.com can be satisfied without a DNS query (arrow 4).

Resolver caching is advantageous for the following reasons:

• You do not need to take any steps to enable resolver caching; it is automatically enabled. As shown in Figure 95 on page 724 and in Figure 96 on page 725, this eliminates the need to manually configure a local name server to cache the DNS responses.

• The cached information can be used by all applications that are running in the z/OS logical partition (LPAR), which provides the performance benefits of caching across the entire system for the cost of one DNS query.

• Resolver caching provides high performance because it reduces the network traffic to name servers.

• The resolver automatically regulates your storage use.

• Cached IP addresses can be returned and reordered in a round-robin manner, which provides a balanced way of using cached resources.

If you have been using a caching-only name server and you want to use resolver caching, see “Migrating from a local caching-only name server to resolver caching” on page 734.

You can disable resolver caching for selected applications; for more information, see “Steps for disabling caching for selected applications” on page 732.

Information that is cached by the resolver

Table 35 on page 725 shows the application programming interfaces (APIs) that use resolver caching.

<table>
<thead>
<tr>
<th>API</th>
<th>Usage</th>
</tr>
</thead>
<tbody>
<tr>
<td>getaddrinfo()</td>
<td>Resolves host name to one or more IP addresses. Supports both IPv4 and IPv6 addresses.</td>
</tr>
<tr>
<td>gethostbyaddr()</td>
<td>Resolves an IP address to a host name. Supports only IPv4 addresses.</td>
</tr>
<tr>
<td>gethostbyname()</td>
<td>Resolves a host name to one or more IP addresses. Supports only IPv4 addresses.</td>
</tr>
<tr>
<td>getnameinfo()</td>
<td>Resolves an IP address to a host name. Supports both IPv4 and IPv6 addresses.</td>
</tr>
</tbody>
</table>
The resolver caches the following DNS response information generated by the APIs in Table 35 on page 725:

- **Forward lookup information (IP addresses as A or AAAA records)**

  *Forward lookups* are host-name-to-IP-address resolution requests. This includes IPv4 (A records) and IPv6 (AAAA records) addressing records from getaddrinfo() and gethostbyname() API calls.

- **Reverse lookup information (domain name pointers as PTR records)**

  *Reverse lookups* are IP-address-to-host-name resolution requests. This includes records from getnameinfo() and gethostbyaddr() API calls.

- **Negative caching (NX) information**

  *Negative caching* is the storage of the knowledge that a record does not exist, or that a request for a specific resource cannot or does not give an answer. The negative cache represents the received NXDOMAIN (nonexistent domain) responses from the server. The negative cache also represents the received NOERROR responses that did not include answer records of the requested type, such as a request for IPv6 addresses when the resource has only IPv4 addresses defined. Negative cache entries represent resources that are known to not exist and they include both reverse and forward entries.

**Notes:**

- IP addresses cached by getaddrinfo() and gethostbyname() API calls can be returned in a round-robin manner if CACHEORDER is enabled.
- Sorting algorithms, such as the SORTLIST statement, might affect the results of the cache reordering logic. See “Interactions of address sorting and cache reordering” on page 730 for more information.

There is an upper limit on the amount of storage that can be used for negative caching information. The upper limit is 20 percent of the maximum amount of cache storage that the resolver is permitted to use. The resolver does not set aside this amount of storage for exclusive use by negative cache entries; rather, the resolver never exceeds this amount of storage to hold negative cache entries. When the upper limit is reached, no subsequent negative cache entries are saved until some existing entries are deleted and the negative cache entry storage use drops below the 20 percent upper limit. For information about setting the maximum amount of cache storage available to the resolver, see “Steps for configuring resolver caching (optional)” on page 731.

The resolver does not cache information retrieved from local host files, such as /etc/hosts and /etc/ipnodes; that type of information is already cached at a process level. The resolver also does not cache information retrieved using an API not listed in Table 35 on page 725.

The length of time that cache entries, including negative entries, are valid depends on the time-to-live (TTL) value that is returned by each domain name server. This is consistent with the behavior when using a caching-only name server or an intermediate name server to resolve a query.

In the following situations, cached entries are not saved up to the TTL value that is returned by the name server:

- When you flush the cache using the MODIFY RESOLVER,FLUSH,ALL command to delete all cached entries (for more information, see “Step for deleting cache entries” on page 734)
- When the maximum allocated storage for the cache is exhausted (for more information, see “Managing the cache size and cache storage” on page 733)
- When you limit the duration of time that any individual cache record can be saved using the MAXTTL resolver setup statement (for more information about the MAXTTL statement, see z/OS Communications Server: IP Configuration Reference)

**The organization of the cached data**

The cache is contained in one physical location that has separate logical structures for forward and reverse lookup information. The cache data is organized by DNS name server, which permits different name servers to provide different values for a given host name or IP address.

For example, consider the installation shown in Figure 97 on page 727. There are two TCP stacks; one TCP stack is used for the core production processing, and a second TCP stack is used for test purposes.
only. The stacks use different name servers to isolate test resources from the production environment. Each name server can potentially have different IPv4 (A record) definitions for the same host name, as is the case for host.ibm.com. If the test application issues a query for host.ibm.com, the test TCP stack directs the request to the test name server, and IP address 10.45.5.5 is obtained. If the production application issues the same query, a different IP address (10.145.5.5) is obtained. The resolver caches both responses but remembers which response was received from which name server, so that a subsequent request from the test application for host.ibm.com returns the correct test IP address, and not the production IP address.

Figure 97. Resolver caching process; each stack specifies one NSINTERADDR value

The resolver performs cache lookups using the NSINTERADDR search order list in the TCPIP.DATA data set. In Figure 97 on page 727, each stack specifies a single NSINTERADDR value. More likely, in reality, multiple NSINTERADDR definitions are provided, as shown in Figure 98 on page 728. In this example installation, if the primary name server is unavailable, a secondary name server is used instead. The resolver considers a cache entry that is associated with any name server in the NSINTERADDR list as a match for the target host name; the name resolution is complete and no DNS queries are sent to any of the name servers. The resolver searches the cache in the order that the name servers appear in the NSINTERADDR list; if multiple entries exist for the same target host name (one from each of the name servers in the NSINTERADDR list), the information provided by the first name server in the list is used. In Figure 98 on page 728, if the test application issues a query for host.ibm.com, IP address 10.145.5.5 is obtained because the first name server IP address in the list is now the production name server (10.6.6.6). If the production application issues the same query, the same IP address, 10.145.5.5 is obtained because there is no entry in the cache for host.ibm.com from the first name server in the list, but there is cache information from the second name server (which is, again, 10.6.6.6).
IPv4 information and IPv6 information are cached as separate entries. A maximum of 35 IP addresses is saved per host name for each name server that provides data for that host name.

**Cache reordering**

DNS servers can be configured to use a round-robin manner for ordering the IP addresses that are returned in response to forward lookup requests. The load balancing that this reordering provides is lost if the resolver does not also reorder its cached list of IP addresses in a round-robin manner. If the resolver does not perform cache reordering, the list of IP addresses is always returned in the same order that the information was received from the DNS server, as long as the cache information remains valid.

Starting in z/OS Communications Server V2R2, you can control whether the resolver reorders the list of cached IP addresses before the resolver returns the list in response to forward lookup resolution requests.

- Use the CACHEREORDER resolver setup statement to enable system-wide cache reordering.
- Use the NOCACHEREORDER resolver setup statement to disable system-wide cache reordering.

You can also disable cache reordering for an individual application by specifying NOCACHEREORDER in the TCPIP.DATA file that the application uses.

**Rules:**

- If both IPv6 and IPv4 addresses are cached for a host name, the two lists of addresses are managed and reordered independently of each other.
- The list of IP addresses is reordered independently of which applications issue the forward lookup requests.
- The list of IP addresses is reordered independently of the type of forward request that the application issues. The forward request can be getaddrinfo() or gethostbyname().
- If system-wide cache reordering is enabled, forward lookup requests from applications that have locally disabled cache reordering have no effect on the round-robin processing.
- If you dynamically change either system-wide or local setting of cache reordering to NOCACHEREORDER, the resolver, on subsequent forward lookup requests, returns the list of IP addresses in the order that the list was cached.
- The resolver performs the cache reordering function before any address sorting is performed. See “Interactions of address sorting and cache reordering” on page 730 for more information.
- Cache reordering has no effect on reverse lookup requests.
**Example**

Consider host name `reorder.domain` that has three IPv6 and four IPv4 addresses that were cached in the following order:

<table>
<thead>
<tr>
<th>IPv6 addresses</th>
<th>2001::10:9:1:1</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>2001::10:9:1:2</td>
</tr>
<tr>
<td></td>
<td>2001::10:9:1:3</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>IPv4 addresses</th>
<th>10.9.1.1</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>10.9.1.2</td>
</tr>
<tr>
<td></td>
<td>10.9.1.3</td>
</tr>
<tr>
<td></td>
<td>10.9.1.4</td>
</tr>
</tbody>
</table>

If system-wide cache reordering is in effect, the resolver reorders the lists as follows for this sequence of forward lookup requests for `reorder.domain`:

1. Application APPLA issues a `getaddrinfo()` request for IPv4 addresses:

<table>
<thead>
<tr>
<th>IPv4 addresses</th>
<th>10.9.1.2</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>10.9.1.3</td>
</tr>
<tr>
<td></td>
<td>10.9.1.4</td>
</tr>
<tr>
<td></td>
<td>10.9.1.1</td>
</tr>
</tbody>
</table>

2. Application APPLD issues a `getaddrinfo()` request for both IPv4 and IPv6 addresses:

<table>
<thead>
<tr>
<th>IPv6 addresses</th>
<th>2001::10:9:1:2</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>2001::10:9:1:3</td>
</tr>
<tr>
<td></td>

</table>

7. Application APPLB issues a `gethostbyname()` request for IPv4 addresses:

<table>
<thead>
<tr>
<th>IPv4 addresses</th>
<th>10.9.1.2</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>10.9.1.3</td>
</tr>
</tbody>
</table>

The resolver 729
8. Application APPLD issues a getaddrinfo() request for both IPv4 and IPv6 addresses:

| IPv6 addresses | 2001::10:9:1:2  
|               | 2001::10:9:1:3  
|               | 2001::10:9:1:1  
| IPv4 addresses | 10.9.1.3  
|               | 10.9.1.4  
|               | 10.9.1.1  
|               | 10.9.1.2  

Notes:

- Because cache reordering does not consider which applications issue the forward lookup requests, an individual application might get results that suggest that cache reordering is not being performed even though it is being performed. For example, the two requests from APPLD result in the same lists even though requests from other applications result in lists with different orders.
- Because NOCACHEORDER is specified in its TCPIP.DATA file, the resolver returns the list of IP addresses in the same order for every request APPLNOCR issues. The requests from APPLNOCR have no effect on the other results where cache reorder is performed.

**Interactions of address sorting and cache reordering**

The resolver can perform the following types of IP address sorting after the resolver obtains the list of IP addresses for a forward lookup request:

- IPv4 addresses are sorted based on the values that are defined on the SORTLIST statement in the application's TCPIP.DATA file. To prevent this kind of sorting, do not specify a SORTLIST statement.
- As part of getaddrinfo() processing, IPv4 and IPv6 addresses are sorted based on the default address selection algorithm. You cannot prevent this sorting from being performed. However, to influence the algorithm, you can define a policy table by using the DEFADDRTABLE statement in the TCP/IP profile. See DEFADDRTABLE statement in z/OS Communications Server: IP Configuration Reference for more information.

When both cache reordering and address sorting are performed, the resolver first reorders the list of IP addresses. The appropriate sorting algorithm is then performed on the reordered list of IP addresses. Depending on the sorting algorithm and the IP addresses in the list, the outcome of the sorting algorithm might cause the resolver to return the list of IP addresses in the same order for every forward lookup request.

For example, if host name sorted.domain resolves to IPv4 addresses 10.9.1.1 and 20.10.8.7, the following results might occur:

- If no SORTLIST statement is coded, half of the resolution requests for sorted.domain have IP address 10.9.1.1 listed first, and half of the requests have IP address 20.10.8.7 listed first.
- If a SORTLIST statement is coded, the results depend on how the sorting algorithm applies to these addresses:
  - If the sorting values on the SORTLIST statement favor one address over the other, the chosen address is always displayed first in the returned list, regardless of cache reordering. For example, if 10.9.1/24 is coded on the SORTLIST statement, IP address 10.9.1.1 is favored and is always first in the sorted list.
  - If the sorting values on the SORTLIST statement do not favor any address, the results are similar to when no SORTLIST statement is defined. For example, if 55.1/16 is coded on the SORTLIST statement, no IP address is favored. Half of the requests have IP address 10.9.1.1 listed first and half have IP address 20.10.8.7 listed first.
**Steps for configuring resolver caching (optional)**

Resolver caching is automatically enabled and you do not need to make parmlib or JCL changes. Unless you choose to do so, you do not have to configure the cache; however, you can explicitly configure resolver caching.

**Before you begin**

You must have already created a resolver setup file; see “The resolver setup file” on page 712 for more information.

**Procedure**

Perform the following steps to configure resolver caching:

1. Specify the CACHE statement to enable system-wide caching of Domain Name System (DNS) queries that have been resolved.
   
   System-wide caching is enabled by default, but you can explicitly enable it by specifying this statement.

2. Specify the CACHESIZE(cachesizeM) statement to define the amount of storage, in megabytes, that can be allocated by the resolver to manage cached records.
   
   The default value is 200 megabytes.
   
   **Guideline:** If you set a CACHESIZE value that is too low, the resolver might repeatedly take action to reduce cache usage. You should set the CACHESIZE value to be at least 50 percent higher than your expected usage.
   
   If you specify this statement and the NOCACHE statement, the CACHESIZE statement is ignored. For more information about cache size, see “Managing the cache size and cache storage” on page 733.

3. Specify the MAXTTL statement to define the maximum amount of time, in seconds, that cache entries are considered to be valid by the resolver.
   
   The default value is the time-to-live (TTL) value that is provided by the name server for this resource. If you specify this statement and the NOCACHE statement, the MAXTTL statement is ignored. For more information about cache size, see “Managing the cache size and cache storage” on page 733.

4. Specify whether cache reordering is used on a system-wide basis.
   
   - Specify CACHEREORDER to enable system-wide cache reordering.
   - Specify NOCACHEREORDER to disable system-wide cache reordering.
   
   The default setting is to disable system-wide cache reordering. If you specify the NOCACHE statement, the CACHEREORDER and NOCACHEREORDER statements are ignored. See “Cache reordering” on page 728 for more information.

5. Perform one of the following steps:
   
   - If the resolver is not active, start the resolver.
   - If the resolver is currently active, issue the MODIFY RESOLVER,REFRESH,SETUP=setup_file_name command to cause the resolver to use the new settings.

**Results**

You complete the task when the correct values for the CACHE, CACHEREORDER or NOCACHEREORDER, CACHESIZE(cachesizeM), and MAXTTL statements are displayed after you issue the START command or in the MODIFY RESOLVER,REFRESH command output.

For more information about resolver setup statements, see z/OS Communications Server: IP Configuration Reference.

For more information about the MODIFY command for the resolver address space, see z/OS Communications Server: IP System Administrator's Commands.
Steps for disabling caching for selected applications
You can disable resolver caching for applications in your environment that do not need to use it.

Before you begin
Some applications might not need to use resolver caching. For example, as shown in Figure 97 on page 727, you might have a production network and a test network in your environment. Users of the test network might require specialized host name resolution using a unique set of DNS servers that are not used in the production network. Because the test network is isolated and is likely to affect only a small number of users, using resolver caching for the test network could waste cache storage, and could complicate operation of the production network by adding information that is not pertinent to the production network. You can disable resolver caching for applications using the test network, while continuing to use resolver caching for the production network.

Procedure
Perform the following steps to disable caching for some applications:
1. Identify or create the TCPIP.DATA data set associated with the application for which you want to disable resolver caching.
2. Turn off the resolver caching function by specifying the NOCACHE statement in that TCPIP.DATA data set.
3. Issue the MODIFY RESOLVER,REFRESH command to cause the resolver to refresh the settings for the application.
4. Activate the Trace Resolver facility to determine which TCPIP.DATA values are being used by the resolver and where they are being read from.
5. When the trace is active, issue the Netstat HOME/-h command to display the values.

Results
The task is completed when the value NOCACHE is displayed in the Trace Resolver output that is generated by the Netstat HOME/-h command.

For more information about configuration statements in TCPIP.DATA, see z/OS Communications Server: IP Configuration Reference. For more information about the MODIFY command for the resolver address space, see z/OS Communications Server: IP System Administrator's Commands.

Steps for disabling cache reordering for selected applications
You can disable cache reordering for applications in your environment if you do not need to use it.

Before you begin
Some applications might not need cache reordering. For example, applications that do not have load balancing requirements or that have that have a well-defined algorithm might require the resolver to return the cached addresses in the same order all the time. Determine which applications do not require cache reordering and disable cache reordering for these specialized applications.

Procedure
Perform the following steps to disable cache reordering for the selected applications:
1. Identify or create the TCPIP.DATA data set that is associated with the application for which you want to disable cache reordering.
2. Turn off the cache reordering function by specifying the NOCACHEORDER statement in the TCPIP.DATA data set.
3. Issue the MODIFY RESOLVER,REFRESH command to refresh the settings for the application.
4. Activate the trace resolver facility to determine which TCPIP.DATA values are being used by the resolver and where the values are read from.
5. When the trace resolver is active, issue the Netstat HOME/-h command to display the values.
Results
Cache reordering is disabled when the value NOCACHEREORDER is displayed in the trace resolver output that the Netstat HOME/-h command generates.

For more information about configuration statements in the TCPIP.DATA data set, see z/OS Communications Server: IP Configuration Reference. For more information about the MODIFY command for the resolver address space, see z/OS Communications Server: IP System Administrator's Commands.

Managing the cache size and cache storage
Resolver cache information is maintained in 64-bit private storage in the resolver address space, which is also referred to as the storage above the 2 GB bar. This means that caching does not impact common storage.

The default maximum size of the cache is 200 megabytes. The size is allocated incrementally, as the cache increases. For planning purposes, assume that 1 megabyte of storage holds between 400 and 450 cache entries. The actual number of cache entries depends on the amount of storage used for cache infrastructure control blocks, which varies depending on the number of name servers and the number of entries. If you want to control the maximum size of the cache instead of using the 200 megabyte default, you can use the CACHESIZE resolver setup statement. The CACHESIZE statement specifies the maximum amount of storage, in megabytes, that can be allocated by the resolver to manage cached records. The CACHESIZE statement is also used to determine the upper limit of storage that can be used for negative cache entries. If you use the default CACHESIZE value of 200M, then no more than 40 megabytes of that storage will be used for negative cache entries.

The resolver does not automatically delete expired records (those records whose TTL value has been exceeded). Regardless of the amount of cache storage that is in use, the resolver deletes expired records if a new request is received for the expired resource. The resolver also deletes expired records when your cache storage usage has reached the following levels, and takes additional actions to reduce your storage usage.

- When cache storage is less than 75 percent full, the resolver deletes all expired records approximately every 10 minutes, without waiting for a new request to be processed.
- When cache storage is 75 - 97 percent full, the resolver deletes all expired records approximately every minute, without waiting for a new request to be processed.
- When cache storage is 98 percent or more full, the resolver deletes all expired records approximately every 30 seconds, without waiting for a new request to be processed. The resolver does not add new records to the cache while usage is greater than 99 percent. Message EZZ9307E is displayed until usage is less than 90 percent, you increase the CACHESIZE value, or you delete the contents of the cache; see “Step for deleting cache entries” on page 734 for more information.

Steps for manually managing the storage capacity of the resolver cache
You can increase the size of the cache, decrease the length of time that cache records are saved in the cache, and delete all cache entries.

Before you begin
You must have already created a resolver setup file; see “The resolver setup file” on page 712 for more information.

Procedure
Perform one of the following steps to manage the storage capacity of the resolver cache:
- On the CACHESIZE statement in the resolver setup file, increase the CACHESIZE value and issue the MODIFY RESOLVER,REFRESH,SETUP=resetup_filename command.
- On the MAXTTL statement in the resolver setup file, decrease the MAXTTL value to decrease the length of time that cache records are saved in the cache and issue the MODIFY RESOLVER,REFRESH,SETUP=resetup_filename command. The new MAXTTL value affects only new cache records as they are created; there is no affect on existing cache records.
- Issue the MODIFY RESOLVER,FLUSH,ALL command to delete all cache entries.
Results
You know you are done when message EZZ9307E is no longer displayed on the operator console.

Step for deleting cache entries
You might want to delete the contents of the cache when an IP address has changed for a given host name or when your cache storage is exhausted.

Procedure
Perform the following step to delete the contents of the cache:
- Issue the MODIFY RESOLVER,FLUSH,ALL command to delete all cache entries.
  For more information about the MODIFY command for the resolver address space, see z/OS Communications Server: IP System Administrator's Commands.

Results
If you have deleted cache entries because your cache storage was exhausted, you know you are done when message EZZ9307E no longer appears on the screen.

Step for displaying the contents of the cache

Procedure
Perform the following step to display the contents of the resolver cache:
- Issue the Netstat RESCache-q command to display the RESCache-q report.
  The Netstat RESCache-q report displays the contents of the resolver cache data. You can display statistical data, both overall and by name server. You can also create a report that shows all the cache entries, or you can use filters to produce a report that shows subsets of cache entries.

What to do next
For details about access control considerations for the Netstat RESCache/-q report, see “Netstat access control” on page 141. For Netstat command syntax and sample report output, see z/OS Communications Server: IP System Administrator's Commands.

Migrating from a local caching-only name server to resolver caching
If you have been using a local caching-only name server, you should consider using resolver caching. You can compare the contents of your local caching-only name server with the contents of the resolver cache by performing these steps.

Before you begin
Resolver caching must be enabled and active. If resolver caching is not enabled (the NOCACHE statement is coded in the resolver setup statement), see “Steps for configuring resolver caching (optional)” on page 731.

Procedure
Perform the following steps to migrate from a local caching-only name server to resolver caching:
1. Display the contents of your caching-only name server and of the resolver cache at specific intervals.
   - For your caching-only name server, you can dump the contents of the DNS cache. For DNS servers running BIND 9, use the zndc dumpdb command.
   - For the resolver cache, use the Netstat RESCache/-q report. For more information, see “Step for displaying the contents of the cache” on page 734.
2. Compare the contents of the caching-only name server and the resolver cache, and determine whether to use only resolver caching or resolver caching with the local caching-only name server, using the following criteria:
• If the contents are similar, and consist primarily of A, AAAA, and PTR DNS records, then you would benefit the most by using only resolver caching. This situation is the most common.

• If the contents are dissimilar, but the caching-only name server has primarily A, AAAA, and PTR DNS records, then the dissimilar contents are most likely the result of differences in how the resolver cache and the caching-only name server delete expired records. In this situation, you are still most likely to benefit from using only resolver caching.

• If the contents are dissimilar, and the caching-only name server has many DNS records that are not A, AAAA, or PTR records, you will probably benefit the most by using both resolver caching and the caching-only name server. This situation is not common.

3. Calculate the amount of resolver cache storage that you think you need.
   You can use the default amount of storage (200 megabytes) or you can use the CACHESIZE resolver setup statement to specify a maximum amount of storage. For calculation purposes, 1 megabyte of storage holds roughly 400 - 450 cache entries.

4. If you are not going to use the local caching-only name server, stop that server.
   **Guideline:** If the local caching-only name server is the only name server in the NSINTERADDR list of name servers to be contacted, replace the caching-only name server entry with one or more name server IP addresses to be contacted. If there is already more than one name server in the NSINTERADDR list of name servers, delete the IP address of the local caching-only name server.

**Results**
For more information about resolver setup statements, see z/OS Communications Server: IP Configuration Reference.

**Monitoring the responsiveness of Domain Name System name servers**

The resolver monitors the responsiveness level of Domain Name System (DNS) name servers that are in the network. The resolver provides two levels of name server monitoring:

• **“Network operator notification” on page 736**

  The resolver alerts the network operator about name servers that fail to respond to a significant percentage of resolver queries, but continues to send DNS queries that are generated by an application to the unresponsive name server. You can use these alerts to better manage the list of name servers that the system uses and to avoid unnecessary delays when a host name or IP address is being resolved.

• **“Autonomic quiescing of unresponsive name servers” on page 738**

  The resolver alerts the network operator about name servers that fail to respond to a significant percentage of resolver queries, and does not send additional DNS queries that are generated by an application to the unresponsive name server. While the name server remains unresponsive, the resolver periodically sends DNS polling queries to the name server. When the name server is responsive to the resolver’s DNS polling queries, the resolver resumes sending DNS queries that are generated by an application to the name server.

To determine name server responsiveness, the resolver collects statistics about name server responsiveness at 30-second or 1-minute intervals, depending on the monitoring function that is being performed. During a given monitoring interval, the resolver keeps system-wide statistics about the total number of resolver queries that are sent to a name server and about the number of those resolver queries that were not responded to by the name server. At the end of the monitoring interval, the resolver calculates a percentage of the total number of queries that were not responded to by the name server over the course of the last interval, or the last five intervals, depending on the monitoring function being performed. This percentage is compared to the setting on the UNRESPONSIVETHRESHOLD resolver setup statement. If the percentage of failures equals or exceeds the threshold value, the resolver considers the name server to be unresponsive. For information about the UNRESPONSIVETHRESHOLD statement and how to set its value, see z/OS Communications Server: IP Configuration Reference and “Optimizing the UNRESPONSIVETHRESHOLD value for your network” on page 741.
The phrase resolver queries does not mean the same thing as resolver API calls in the context of name server responsiveness. A single resolver API call, such as getaddrinfo() or gethostbyname(), can generate multiple resolver queries to one or more DNS name servers, based on retry counts, domain names to append to a search, or the type of information that is being requested by the API. Conversely, a resolver API call might not generate any resolver queries to any DNS name servers, if the resource is already in the resolver cache. See “Examples of resolver monitoring of DNS name servers” on page 740 for examples of how different TCPIP.DATA file settings can influence name server responsiveness statistics.

**Restriction:** The resolver can monitor a maximum of 32 name servers for responsiveness.

The resolver considers the following failures to be indicative of an unresponsive name server:

- The resolver sends a UDP or TCP query to a name server and never receives a response.
- The resolver sends a UDP query to a name server and receives a response after the RESOLVERTIMEOUT value has expired.
- The resolver attempts to send data to a name server using UDP, but the data cannot be sent to the target IP address (for example, because of an error in the route configuration).
- The resolver attempts to connect to a name server using TCP, but the connection attempt times out.
- In some situations, the BIND 9 DNS utilities (for example, dig or nsupdate) issue getaddrinfo() API calls to resolve a host name that represents a remote DNS name server, and those API calls invoke z/OS resolver processing. If any of the previously mentioned failures occur during these BIND 9 resolver calls, the failures are included in the name-server statistics.

The resolver does not consider the following failures to be indicative of an unresponsive name server:

- The resolver cannot open a socket (UDP or TCP) to send a request to a name server, including instances in which the system is IPv4-only capable and an IPv6 name server IP address is coded on the NSINTERADDR statement.
- The resolver sends a UDP query to a name server to determine whether the name server is EDNS0-capable, but does not receive a response to that UDP query; see “Extension Mechanisms for DNS standards and the resolver” on page 743 for more information about EDNS0 processing.
- The resolver sends a UDP query to a name server and the name server responds with a DNS return code (such as SERVFAIL or NOTIMPL) that indicates that the name server is active and responding but is unable to process the request that was sent.
- Timeouts or failures occur during BIND 9 DNS utility processing that does not involve getaddrinfo() calls (that processing uses BIND 9 resolver services to send queries to a name server).

**Network operator notification**

You can specify only a failure threshold percentage using the UNRESPONSIVETHRESHOLD resolver setup statement, or you can use the default value, which is 25%. In either case, the resolver reacts to unresponsive name servers by notifying the network operator of the condition and continues to send DNS queries to the unresponsive name server. The network operator notification function collects name-server statistics at 1-minute intervals, but makes decisions based on the last five monitoring intervals. These intervals are called sliding 5-minute windows.

**Messages generated by the resolver for the network operator notification function**

If the resolver detects that a name server is not being responsive, a series of network operator messages is issued that relate to that name server. For example, if a name server is operating at IP address 10.42.35.200 and the UNRESPONSIVETHRESHOLD value is 25, then the following sequence of messages might be generated by the resolver:

1. At the end of a 5-minute monitoring interval, the resolver determines that the name server failed to respond to 35% of 6000 queries that were attempted by the resolver. The resolver considers the name server to be unresponsive and issues the following messages:

   
   **EZ9308E** UNRESPONSIVE NAME SERVER DETECTED AT IP ADDRESS 10.42.35.200
   **EZ9310I** NAME SERVER 10.42.35.200
   TOTAL NUMBER OF QUERIES SENT 6000

   

2. At the end of the next 5-minute interval, the resolver determines that the name server failed to respond to 55% of the 3000 queries that it attempted during that interval. The name server is still considered to be unresponsive, and the following message is issued:

```
EZZ9310I NAME SERVER 10.42.35.200
TOTAL NUMBER OF QUERIES SENT 3000
TOTAL NUMBER OF FAILURES 1650
PERCENTAGE 55%
```

This message and the statistical information for the name server are issued at 5-minute intervals for as long as the resolver considers the name server to be unresponsive.

3. At the end of a subsequent monitoring interval, the resolver determines that the name server failed to respond to 15% of the 4500 queries that the resolver attempted during the latest sliding 5-minute interval. This percentage is under the threshold value, so the resolver considers this name server to be responsive again. The resolver clears message EZZ9308E from the operator console and issues the following messages:

```
EZZ9309I NAME SERVER IS NOW RESPONSIVE AT IP ADDRESS 10.42.35.200
EZZ9310I NAME SERVER 10.42.35.200
TOTAL NUMBER OF QUERIES SENT 4500
TOTAL NUMBER OF FAILURES 675
PERCENTAGE 15%
```

4. The resolver also clears message EZZ9308E from the operator console if any of the following situations occur:

- The network operator disables the monitoring function using the MODIFY RESOLVER,REFRESH,SETUP command. For more information, see “Steps for modifying the UNRESPONSIVETHRESHOLD value” on page 743.
- The network operator enables the autonomic quiescing of unresponsive name servers function using the MODIFY RESOLVER,REFRESH,SETUP command. For more information, see “Steps for modifying the UNRESPONSIVETHRESHOLD value” on page 743.
- No resolver queries are sent to the name server during the current 5-minute monitoring interval.
- The network operator notification function abnormally terminates due to system error.
- The resolver is stopped.

The resolver issues individual messages for each name server that it considers to be unresponsive at the end of a given monitoring interval. Because the resolver calculates the responsiveness of a name server by using a sliding 5-minute interval, messages might be issued for different name servers at different times, rather than notifications about all unresponsive name servers being issued at the same time.

**Diagnosing problems with unresponsive name servers**

Use the statistics supplied in message EZZ9310I to determine the severity of the problem that the resolver is reporting. For example, if the unresponsive name server is the primary server for the network, and it is failing to respond to over half of a large number of queries that are directed to it, that situation might be more serious than a secondary name server that is not responding to 25% of a small number of queries. You can also use the statistics that are displayed when message EZZ9309I is issued to determine whether the name server is fully responsive again, is likely to become unresponsive again because the failure rate is still close to the threshold value, or is just not being used in your environment.

**Guideline:** The resolver does not require that there be a certain number of failed queries to a particular name server before it declares that server to be unresponsive. For example, if only one query is received by a particular name server during a monitoring interval, and that query fails to obtain a response, then the resolver considers that name server to be 100% unresponsive.
**Autonomic quiescing of unresponsive name servers**

In addition to specifying a failure threshold percentage on the UNRESPONSIVETHRESHOLD resolver setup statement, you can also specify the AUTOQUIESCE operand. If you specify the AUTOQUIESCE operand, in addition to network operator notification, the resolver stops sending DNS queries that are generated by an application to the unresponsive name server. While a name server is considered to be unresponsive, the resolver sends DNS polling queries to the name server every 6 seconds. When the name server is responsive to the resolver’s DNS polling queries, the resolver resumes sending DNS queries that are generated by an application to the name server. The autonomic quiescing of unresponsive name servers function collects name-server statistics in intervals of 30 seconds, but makes decisions based on no more than two monitoring intervals.

**Guideline:** If all name servers specified on the TCPIP.DATA NSINTERADDR statements are unresponsive, the resolver sends DNS queries that are generated by an application to those name servers; the resolver does not fail the application queries immediately.

**Restriction:** If you specify the AUTOQUIESCE operand on the UNRESPONSIVETHRESHOLD statement, you must also specify the GLOBALTCPIPDATA statement. If you do not specify the GLOBALTCPIPDATA statement, the resolver issues message EZD2036I and ignores the AUTOQUIESCE operand. The resolver operates as if you requested the network operator notification function. For more information about the UNRESPONSIVETHRESHOLD statement, see z/OS Communications Server: IP Configuration Reference.

If you use multiple TCP/IP stacks in a common INET (CINET) environment, you must ensure that the IP addresses of the name servers that are specified in the global TCPIP.DATA file are accessible from all TCP/IP stacks. If a name server IP address is accessible only from a specific TCP/IP stack, the autonomic quiescing function could mistakenly consider that name server as unresponsive to DNS queries. For example, consider two TCP/IP stacks, TCPIP1 and TCPIP2, where the IP address for DNS1 is accessible using only TCPIP1 and the IP address for DNS2 is accessible using only TCPIP2. If the NSINTERADDR statement in the global TCPIP.DATA specifies DNS1 and DNS2, in that order, any application DNS queries with stack affinity to TCPIP2 results in DNS query failures to DNS1 because the IP address for DNS1 is not accessible using TCPIP2. If there is a sufficient volume of these queries with stack affinity to TCPIP2, or the UNRESPONSIVETHRESHOLD value is very small, the resolver might decide that DNS1 is unresponsive and stop using it temporarily, resulting in unnecessary failures for application DNS queries that use TCPIP1.

**Guideline:** If you cannot ensure that all DNS IP addresses are accessible from all your TCP/IP stacks, you should not use a global TCPIP.DATA file, and you should not code AUTOQUIESCE on the UNRESPONSIVETHRESHOLD setup statement in your resolver setup file.

**Messages generated by the resolver for the autonomic quiescing of unresponsive name servers function**

If the resolver detects that a name server is not being responsive, a series of network operator messages is issued that relate to that name server. For example, if a name server is operating at IP address 10.42.35.200 and the UNRESPONSIVETHRESHOLD value is 100, then the following sequence of messages might be generated by the resolver:

1. At the end of a 30-second monitoring interval, the resolver determines that the name server failed to respond to 100% of the 500 queries that were attempted by the resolver. The resolver considers the name server to be unresponsive and issues the following messages:

   EZZ9311E STOPPED USING NAME SERVER AT IP ADDRESS 10.42.35.200
   EZZ9313I NAME SERVER 10.42.35.200
   TOTAL NUMBER OF QUERIES SENT 500
   TOTAL NUMBER OF FAILURES 500
   TOTAL NUMBER OF RESOLVER POLLS SENT 0
   TOTAL NUMBER OF POLL FAILURES 0
   PERCENTAGE 100%

   After issuing this message, the resolver sends only DNS polling queries to the unresponsive name server.

2. At the end of a subsequent monitoring interval, the resolver determines that the name server failed to respond to 10% of the 10 or more DNS polling queries during the last two monitoring intervals. This percentage is below the 100% threshold value, so the resolver considers this name server to be...
responsive again. The resolver clears message EZZ9311E from the operator console and issues the following message:

```
EZZ9312I RESUMED USING NAME SERVER AT IP ADDRESS 10.42.35.200
```

3. After the resolver issues message EZZ9312I, it resumes sending DNS queries that are generated by an application to the name server.

4. The resolver also clears message EZZ9311E from the operator console if any of the following events occur:

   • The network operator disables the monitoring function using the MODIFY RESOLVER,REFRESH,SETUP command. For more information, see “Steps for modifying the UNRESPONSIVETHRESHOLD value” on page 743.
   • The network operator enables the network operator notification function using the MODIFY RESOLVER,REFRESH,SETUP command. For more information, see “Steps for modifying the UNRESPONSIVETHRESHOLD value” on page 743.
   • The autonomic quiescing of unresponsive name servers function abnormally terminates because of a system error.
   • The resolver is stopped.

The resolver issues individual messages for each name server that it considers to be unresponsive at the end of a given monitoring interval. Because the resolver calculates the responsiveness of a name server at every interval, messages might be issued for different name servers at different times, rather than notifications being issued about all unresponsive name servers at the same time. The resolver does not periodically reissue message EZZ9313I for each name server, but the status and current failure rate for each name server specified on an NSINTERADDR statement in the global TCPIP.DATA file is included in the MODIFY RESOLVER,DISPLAY command output when the autonomic quiescing function is active. The failure rate that is displayed is the percentage calculated by the resolver for the individual name server at the end of the last 30-second monitoring interval. For more information about the MODIFY command for the resolver address space, see z/OS Communications Server: IP System Administrator’s Commands.

**Guideline:** In most cases, the resolver requires a sample size of at least 10 DNS queries before it declares a name server to be either unresponsive or responsive. For example, if only one query is received by a particular name server during a 30-second monitoring interval, and that query fails to obtain a response, then the resolver does not consider that name server to be unresponsive, even though the failure rate is 100% and exceeds the UNRESPONSIVETHRESHOLD value. The resolver sends DNS polling queries to this name server to collect a sufficient sample size of responses. In subsequent intervals, the resolver uses the results from DNS queries that are generated by an application and from DNS polling queries to calculate the overall failure rate for the name server.

**How the resolver polls unresponsive name servers**

The resolver sends DNS polling queries to unresponsive name servers every 6 seconds. The resolver uses the value specified on the RESOLVERTIMEOUT statement in the global TCPIP.DATA file to determine how long to wait for a response to a given DNS polling query. If the RESOLVERTIMEOUT value is greater than 6, multiple DNS polling queries can be outstanding to a given name server.

**Rule:** If you change the value of the RESOLVERTIMEOUT statement, only the timeout value of subsequent DNS polling queries is affected. For more information about the RESOLVERTIMEOUT statement, see z/OS Communications Server: IP Configuration Reference.

The resolver continues to poll unresponsive name servers until one of the following events occur:

   • The name server responds to all DNS queries generated by an application and to all DNS polling queries.

   If a name server is unresponsive, the only queries that the resolver sends to the name server are DNS polling queries. The resolver sends DNS queries generated by an application to the name server as soon as the name server is responsive to DNS polling queries, but the resolver continues polling a name server as long as some DNS queries result in failures. The resolver considers a name server to be responsive to DNS polling queries if one of the following situations occur:
- If the name server had responded to DNS queries that are generated by an application prior to becoming 100% unresponsive to these queries, a single positive response to a DNS polling query is sufficient for the name server to be considered responsive.

- In all other cases, the name server must respond to a sufficient percentage of DNS polling queries to ensure that the following conditions are true:
  
  - At least 10 DNS polling queries received positive responses or timed out within the last 60 seconds
  
  - The failure rate for this name server in terms of responding to DNS polling queries is less than the `UNRESPONSIVETHRESHOLD` percentage.

Any response from the name server to a DNS polling query is considered to be a positive response, including responses that specify NXDOMAIN, SERVFAIL, or similar responses.

- The autonomic quiescing of unresponsive name servers is stopped with a MODIFY REFRESH,SETUP command. For more information about the MODIFY command for the resolver address space, see z/OS Communications Server: IP System Administrator's Commands.

- The name server is removed from the list of name servers that is specified on the NSINTERADDR statements in the global TCPIP.DATA file. The resolver stops polling this name server whether the server was explicitly removed from the list by the network operator using a MODIFY REFRESH command or implicitly removed as a result of a DNS query generated by an application. For more information about the MODIFY command for the resolver address space, see z/OS Communications Server: IP System Administrator's Commands.

- The resolver is stopped.

Examples of resolver monitoring of DNS name servers

Values in the TCPIP.DATA file can affect the statistics that the resolver collects when it monitors DNS name servers. For example, consider the following settings from TCPIP.DATA:

<table>
<thead>
<tr>
<th>NAMESERVER</th>
<th>10.43.25.200</th>
<th>10.43.125.203</th>
<th>10.43.25.200</th>
</tr>
</thead>
<tbody>
<tr>
<td>RESOLVERUDPRETRIES</td>
<td>2</td>
<td></td>
<td></td>
</tr>
<tr>
<td>RESOLVERTIMEOUT</td>
<td>0.975</td>
<td></td>
<td></td>
</tr>
<tr>
<td>RESOLVEVIA</td>
<td>UDP</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

In this example, one name server (10.43.25.200) appears twice in the list of name servers that the resolver will search. The resolver should try that list of name servers again one time before it considers the name servers to be unresponsive. Assume that the resolver generates a query to resolve the address user.ibm.com as part of gethostbyname processing. The following example sequence occurs:

1. The resolver sends the query to name server 10.43.25.200, which times out after 75 milliseconds (based on the RESOLVERTIMEOUT value).

2. The resolver forwards the request to name server 10.43.125.203, which also times out.

3. The request goes to name server 10.43.25.200 a second time (as the last name server in the list), which times out again.

   The first retry of the list name servers is complete.

4. The resolver begins at the top of the list again and sends the request to name server 10.43.25.200 for a third time. A response arrives from this name server, possibly as the result of name server delays.

5. The resolver stops searching for the resource.

Based on the search that the resolver performed, the system-wide total request count for name server 10.43.25.200 is incremented by 3, and the total failure count is incremented by 2. If the searches that are shown in this example are all the activity for this name server over the course of a 5-minute sliding window or the 30-second monitoring interval, the failure rate for this name server is 66%; the system-wide total request count and the total failure count for name server 10.43.124.203 are both incremented by 1. If the resolver does not send any more queries to this name server during the 5-minute sliding window or the 30-second monitoring interval, the failure rate for name server 10.43.124.203 is 100%.
If you are using the network operator notification and the threshold percentage is less than 66%, the resolver reports both of these name servers as unresponsive, but continues to send DNS queries to both name servers.

If you are automatically quiescing unresponsive name servers, the resolver does not consider either of these name servers to be unresponsive because less than 10 queries were directed to the name server during the 30-second interval. The name servers are not considered unresponsive regardless of the setting of the UNRESPONSIVETHRESHOLD value.

Consider these different TCPIP.DATA file settings:

<table>
<thead>
<tr>
<th>NAMESERVER: 10.43.25.200</th>
</tr>
</thead>
<tbody>
<tr>
<td>SEARCH raleigh.ibm.com</td>
</tr>
<tr>
<td>RESOLVERTIMEOUT 0.075</td>
</tr>
<tr>
<td>RESOLVEVIA UDP</td>
</tr>
</tbody>
</table>

In this example, only one name server is coded, and only one domain name can be appended to the input host name as an additional search attempt. Assume that an application issues getaddrinfo() for host name user, and that ai_family=AF_UNSPEC is specified. The following example sequence occurs:

1. The resolver searches for domain name user.raleigh.ibm.com and requests AAAA records.
2. One of the following actions occurs:
   - If the resolver obtains resource information, the search ends.
   - If the resolver does not obtain resource information, the resolver continues to request AAAA records, but searches the next domain in the sequence, which is user.
3. One of the following actions occurs:
   - If the resolver obtains resource information, the search ends.
   - If the resolver does not obtain resource information, the resolver searches for domain name user.raleigh.ibm.com and requests A records.
4. One of the following actions occurs:
   - If the resolver obtains resource information, the search ends.
   - If the resolver does not obtain resource information, the resolver continues to request A records, but searches the next domain in the sequence, which is user.

If the name server at 10.43.25.200 fails to respond to all of the queries, the system-wide total request count and the total failure count for this name server are incremented by 4. The network operator notification function would consider this name server to be unresponsive (because it experienced a 100% failure rate), but the autonomic quiescing of unresponsive name servers function would not (because less than 10 requests were directed to the name server). If this query were repeated three times within the 30-second monitoring interval and the total request count and total failure count for this name server was 12 and not 4, then the autonomic quiescing of unresponsive name servers function would consider this name server to be unresponsive because more than 10 queries were directed to the name server.

Optimizing the UNRESPONSIVETHRESHOLD value for your network

Once every monitoring interval, the resolver calculates the percentage of queries to a name server that failed in the previous 30-seconds or 5 minutes, and then compares this percentage to the threshold value that you set in the UNRESPONSIVETHRESHOLD statement to determine whether that DNS name server is unresponsive. If the resolver sends a query to a name server multiple times and the name server does not respond to multiple queries, each query is considered to be a unique failure to respond. When you specify the UNRESPONSIVETHRESHOLD value, consider the following factors that have an impact on the effectiveness of your setting:

- If you specify a small percentage for this value, an excessive number of operator notifications might occur. Short network disruptions that occur during the 30-second or 5-minute monitoring interval might result in some undeliverable resolver queries or name server responses, and a low threshold value might cause the resolver to alert the operator, and possibly stop using the name server, unnecessarily.
• If you specify a large percentage for this value, persistent issues with the network or the name server might be undetected even though a significant portion of resolver queries are not being processed by the name server.

• The setting on the RESOLVERTIMEOUT statement in the TCPIP.DATA file also affects the value that you should specify for the UNRESPONSIVETHRESHOLD setting. If you set a very short timeout value, even slight network disruptions might cause name server responses to be delayed longer than the amount of time specified by the RESOLVERTIMEOUT value. These delays are considered to be non-responses from the name server, which might cause unnecessary messages to be generated for this name server. A less aggressive (higher) percentage setting for the UNRESPONSIVETHRESHOLD value might be warranted in such a situation.

• The settings of the RESOLVERUDPRETRIES, SEARCH, and NAMESERVER statements in the TCPIP.DATA file can also contribute to high numbers of apparent failures on the part of the name server. See “Examples of resolver monitoring of DNS name servers” on page 740 for information about how these settings can influence the statistics that are collected by the resolver.

Guideline: When you set the optimal threshold by determining the error rate for a given name server, determine the error rate before you activate the autonomic quiescing of unresponsive name servers function.

One strategy that you can use to select the most optimal threshold value is to start with the default setting, which is 25%, and determine how many network operator messages are issued, if any, during normal operation of the network.

• If your network is operating in an acceptable manner (for example, no performance issues are detected and no host name or IP address resolutions delays are detected), examine the number of network operator alerts that are generated by the resolver:
  – If the number of network operator messages is zero or insignificant, leave the setting at the default value, or even decrease the threshold value slightly.
  – If the number of network operator messages is excessive, which suggests that a lot of false negative conditions were detected by the resolver, increase the threshold setting until the number of messages that is generated is appropriate for your network.

• If the name server is now responsive, but the failure rate is just slightly below the threshold value, the name server will probably become unresponsive again with a minor disruption in the network. If your network is currently operating in a satisfactory manner, consider increasing the threshold setting so that the resolver issues EZZ9308E messages only when your network conditions change significantly. Use the statistics that are displayed when message EZZ9309I is issued to modify the threshold setting to a more optimal value.

• If your network is experiencing performance issues that resolver delays might be contributing to (for example, unexplained application delays), consider decreasing the responsiveness threshold setting to determine whether issues with the name servers are being detected by the resolver but are not being reported as unresponsive. If this lower threshold value causes the resolver to generate network operator messages that identify name servers that are unresponsive and that are impacting network operations, consider using this lower value for normal operations to provide more timely identification of name server issues.

A second strategy that you can use to select the most optimal threshold value is to start with the lowest threshold setting, which is 1%. If your name servers are failing to respond to a small percentage of the overall resolver queries that are being sent, the resolver generates EZZ9308E messages. At 5-minute intervals, the resolver also generates EZZ9310I messages, which indicate the percentage of failures for the most recent 5-minute sliding window. Use the EZZ9310I messages to determine the highest failure rate during normal operation of the network, and then set the threshold value to that rate, or to a value slightly above that rate. For example, if the highest failure percentage displayed on the EZZ9310I messages is 4%, set the threshold value to 5% for your network. This value ensures that the resolver considers name servers to be unresponsive only when they experience a failure rate that is greater than the rate that typically occurs in your network.
Steps for modifying the UNRESPONSIVETHRESHOLD value
You can modify your threshold value and restart or refresh the resolver.

Before you begin
You must have already created a resolver setup file; see “Steps for creating a resolver setup file” on page 716 for instructions.

Procedure
Perform the following steps to modify the UNRESPONSIVETHRESHOLD value.

1. Specify the UNRESPONSIVETHRESHOLD value that you want to use in the resolver setup file:
   • To disable the monitoring function, specify UNRESPONSIVETHRESHOLD(0).
   • To notify the network operator, specify UNRESPONSIVETHRESHOLD(percentage), where percentage is a value in the range 1 - 100. Do not specify the AUTOQUIESCE operand on the UNRESPONSIVETHRESHOLD statement.
   • To automatically quiesce unresponsive name servers, specify UNRESPONSIVETHRESHOLD(percentage,AUTOQUIESCE), where percentage is a value in the range 1 - 100.

   Rule: If you do not specify the UNRESPONSIVETHRESHOLD statement in the resolver setup file, the resolver notifies the network operator using the default value, which is 25%.

2. Perform one of the following steps:
   • If the resolver is not active, start the resolver.
   • If the resolver is currently active, issue the MODIFY RESOLVER,REFRESH,SETUP=setup_file_name command to cause the resolver to use the new threshold setting.

   If you did not specify the AUTOQUIESCE operand on the UNRESPONSIVETHRESHOLD statement, the new percentage value is used at the end of the next sliding 5-minute interval to determine name server responsiveness.

   If you specified the AUTOQUIESCE operand on the UNRESPONSIVETHRESHOLD statement, the new percentage value is used at the end of the next 30-second interval to determine name server responsiveness.

Results
You know you are done when the correct UNRESPONSIVETHRESHOLD value and AUTOQUIESCE values are displayed after you issue the START command or the correct values are displayed in the MODIFY RESOLVER,REFRESH command output.

Extension Mechanisms for DNS standards and the resolver
The resolver can use UDP protocols to more efficiently obtain resource information when it uses the Extension Mechanisms for DNS (EDNS0) standards. Before these standards existed, UDP responses from a name server were limited to 512 bytes. If a large number of resource records appear on a DNS response message, more than 512 bytes might be required to return all the response data to the resolver. IPv6 resource records are larger than IPv4 resource records, so fewer IPv6 resource records are needed to reach the 512 byte limitation, but the limitation can be reached even with just IPv4 resource records. EDNS0 support permits the resolver to accept DNS messages, using UDP protocols, of greater than 512 bytes, if the name server that is providing the response message also supports EDNS0.

   • If the name server does not support EDNS0, these larger responses are truncated to fit within 512 bytes of UDP packet data, and the resolver resends the request using TCP protocols to acquire the entire response message.
   • If the name server does support EDNS0, the resolver accepts up to 3072 bytes of DNS response message data in a single UDP packet.
You do not need to configure support for EDNS0 standards. If the resolver is not certain of the EDNS0 capability of a name server, the resolver does not use EDNS0 for that name server and does not indicate on any query that it sends to the name server that it supports EDNS0 processing. After the resolver dynamically determines that a name server supports EDNS0 processing, the resolver modifies the DNS requests that are sent to the name server to use EDNS0.

The resolver dynamically attempts to determine the EDNS0 capabilities of a name server the first time that the resolver receives a truncated UDP response from the name server; the resolver sends the same query to the name server and includes an indication that it supports EDNS0 processing, which is called an EDNS0 probe. The resolver determines whether the name server supports EDNS0 based on the following possible results from the EDNS0 probe:

- If the name server response to the EDNS0 probe indicates that the name server also supports EDNS0, the resolver uses EDNS0 on all subsequent queries to that name server.
- If the name server response to the EDNS0 probe indicates that the name server does not support EDNS0, the resolver does not use EDNS0 on subsequent queries to that name server.
- If the resolver does not receive a response before the timeout period expires, it does not use EDNS0 on subsequent queries to that name server.

No response can indicate any of the following conditions:
- The RESOLVERTIMEOUT value was too small for the larger UDP packet to be received in time
- The name server ignored the EDNS0 probe query
- A network router along the path from the name server to the resolver is discarding UDP packets greater than 512 bytes even though the name server and the resolver both support EDNS0

Because the resolver cannot determine why a timeout occurs, it does not use EDNS0 to that name server for a minimum five-minute interval. At the end of that interval, if appropriate, the resolver sends another EDNS0 probe query to determine whether the name server now supports EDNS0. To fully gain EDNS0 performance benefits, you should choose a resolver timeout value that is long enough to allow larger UDP packets to arrive.

The resolver periodically verifies that the name server does not support EDNS0, even if the response to the EDNS0 probe explicitly indicated that the name server does not support EDNS0. The periodic EDNS0 probe processing allows the resolver to dynamically discover that the capabilities of the name server have changed, although the rediscovery period might take some time. You can use the MODIFY RESOLVER,REFRESH command to cause the resolver to rediscover the capabilities of the name servers more quickly. For more information about the MODIFY RESOLVER,REFRESH command, see z/OS Communications Server: IP System Administrator's Commands.

To verify whether a name server supports EDNS0, use the `dig` command with the `+bufsize=` option to force `dig` to send an OPT RR record on the request. If the name server supports EDNS0, it responds with its own OPT RR record on the response.

If you have upgraded a name server to support EDNS0, you can issue the MODIFY RESOLVER,REFRESH command to force the resolver to dynamically determine name server capability. The resolver can then use EDNS0 support to accept DNS messages of greater than 512 bytes, using the less costly UDP protocol, which results in improved DNS and resolver performance.

### Resolver configuration files

Understanding the resolver search orders used in native MVS and z/OS UNIX environments is key to setting up your system properly.

The resolver can use available name servers, local definitions, or a combination of both, to process API resolver requests. Figure 99 on page 745 shows how local definitions can be specified and searched for when needed.

Use the Trace Resolver facility to determine what TCPIP.DATA values are being used by the resolver and where they were read from. For information about dynamically starting the trace or using the Resolver...
The resolver collects Trace Resolver output, see z/OS Communications Server: IP Diagnosis Guide. After the trace is active, issue the Netstat HOME/-h command to display the values. You can issue a Ping of a host name from TSO and from the z/OS UNIX shell to show the activity to the resolver cache and to any DNS servers that might be configured.

The actual search order of the candidate files varies depending on the type of API that is used and the resolver setup. The search orders are explained in more detail in “Search orders used in the z/OS UNIX environment” on page 751 and “Search orders used in the native MVS environment” on page 755. Because the resolver runs in the address space of the application, the resolver accesses the candidate files from the application address space.

Use the Trace Resolver facility to obtain information about an application's search order. Trace Resolver output provides a caller API value that determines which search order is used. For information about dynamically starting the trace or using the Resolver CTRACE function to collect Trace Resolver output, see z/OS Communications Server: IP Diagnosis Guide.

The following caller API values indicate the z/OS UNIX environment search order is used:
- Language Environment C Sockets
- UNIX System Services [z/OS UNIX System Services (z/OS UNIX) callable services]

The following caller API values indicate the native MVS environment search order is used:
- TCP/IP C Sockets
- TCP/IP Pascal Sockets
- TCP/IP Rexx Sockets
- TCP/IP Sockets Extended

The following commands are some examples of Communications Server TSO commands that use the native MVS search order:
- DIG
- FTP (batch only)

**Rule:** Batch FTP jobs use //SYSTCPD if it is specified. If //SYSTCPD is not specified, then the z/OS UNIX search order is used.
- LPR
- NETSTAT
- NSLOOKUP
- PING
- REXEC
- RPCINFO
- RSH
- TRACERTE
The following commands are some examples of Communications Server UNIX commands that use the z/OS UNIX search order:

- dig
- dnsdomainname
- domainname
- ftp

**Rule:** The TSO FTP command also uses the z/OS UNIX search order.
- host
- hostname
- netstat
- nslookup
- ping
- rexec
- rpcinfo
- snmp
- traceroute

The following applications are some examples of Communications Server applications that use the native MVS search order:

- CICS Listener
- LPD
- Miscellaneous server
- PORTMAP
- RSHD
- TN3270E Telnet server

The following applications are some examples of Communications Server applications that use the z/OS UNIX search order:

- CSSMTP
- FTP
- SNMP agent
- z/OS UNIX OPORTMAP
- z/OS UNIX OREXECD
- z/OS UNIX ORSHD

**z/OS XL C/C++ environment variables for configuration files**

A z/OS XL C/C++ environment variable is an identifier used like a variable in a program. In Table 36 on page 746, the following environment variables appear:

**HOSTALIASES**
The host aliases data set, file, or ddname.

**RESOLVER_CONFIG**
The resolver configuration data set, file, or ddname. The RESOLVER_CONFIG environment variable is used by TCP/IP to include the name of an MVS data set or z/OS UNIX file in the search order for TCPIP.DATA.

**RESOLVER_IPNODES**
The IPNODES data set, file, or ddname.
X SITE and X ADDR
The HOSTS.SITEINFO and HOSTS.ADDRINFO data sets or ddnames created by the MAKESITE TSO command. The X SITE environment variable influences how gethostbyname() resolves the network address of the specified host name. The X ADDR environment variable is used by some TCP/IP functions, such as getnetbyaddr(), to include the name of an MVS data set or z/OS UNIX file in the search order for the HOSTS.ADDRINFO data set.

X_XLATE
The ASCII-EBCDIC translate table data set or ddname created by the CONVXLAT TSO command. The X_XLATE environment variable is used by TCP/IP to include the name of an MVS data set or z/OS UNIX file in the search order for the STANDARD.TCPXLBIN data set.

Other environment variables that can be explicitly set by the resolver include the following variables:

LOCALDOMAIN
Defines the domain origin. When this environment variable is set, it overrides any setting for DOMAIN, DOMAINORIGIN, or SEARCH found in TCPIP.DATA

RESOLVER_TRACE
Defines the data set, file, or ddname into which the resolver trace output is written.

MESSAGECASE
Determines whether messages are translated to all uppercase characters before being sent to the console.

Setting z/OS XL C++ environment variables
The method that you use to set z/OS XL C++ environment variables so that a z/OS XL C++ UNIX application is able to retrieve the value depends on whether you start the application from the z/OS shell or from JCL. The following general methods apply to all environmental variables; the examples are specific to the RESOLVER_CONFIG environmental variable.

Setting z/OS XL C/C++ environment variables from the z/OS shell
If you are starting the z/OS XL C++ UNIX application from the z/OS shell, you must set the environment variables using the export shell command. You can specify either the file name or the data set name, as shown in the following two examples for setting the RESOLVER_CONFIG environment variable:

- To set the value of the RESOLVER_CONFIG environment variable to the file name /etc/tcpa.data, specify the following export command:

  ```
  export RESOLVER_CONFIG=/etc/tcpa.data
  ```

- To set the RESOLVER_CONFIG environment variable to the data set TCPA.MYFILE(TCPDATA), specify the following export command.

  ```
  export RESOLVER_CONFIG="/'TCPA.MYFILE(TCPDATA)'"
  ```

Rule: You must put single quotation marks around the data set name. If you do not, your user ID will be added as a prefix to the data set name when the resolver tries to open the file.

Setting z/OS XL C/C++ environment variables from JCL
If you are starting the z/OS XL C++ UNIX application from JCL, you must code the environment variable as a parameter in the JCL of the application, as shown in the following examples:

- This example shows setting the RESOLVER_CONFIG environment variable to a z/OS UNIX file:

  ```
  //OSNMPD    PROC
  //*
  //* Procedure for running the SNMP agent
  //*//OSNMPD EXEC PGM=EZASNMPD,REGION=4096K,TIME=NOLIMIT,
  // PARM=('POSIX(ON) ALL31(ON)
  // ' ENVAR("RESOLVER_CONFIG=/etc/tcpa.data")/-d 0')
  ```
This example shows setting the RESOLVER_CONFIG environment variable to an MVS partitioned data set:

```c
//OSNMPD    PROC
/*
* Procedure for running the SNMP agent
*/
//OSNMPD EXEC PGM=EZASNMPD,REGION=4096K,TIME=NOLIMIT,
// PARM=('POSIX(ON) ALL31(ON)',
// 'ENVAR("RESOLVER_CONFIG=\'\'TCPA.MYFILE(TCPDATA)\''\')/-d 0')
```

This example shows setting the RESOLVER_CONFIG environment variable to a DD card:

```c
//OSNMPD PROC
/*
* Procedure for running the SNMP agent
*/
//OSNMPD EXEC PGM=EZASNMPD,REGION=4096K,TIME=NOLIMIT,
// PARM=('POSIX(ON) ALL31(ON)',
// 'ENVAR("RESOLVER_CONFIG=DD:TCPDATA")/-d 0')
//TCPDATA DD DSN=TCPA.MYFILE(TCPDATA),DISP=SHR
```

**Tip:** You can also specify a ddname as `//DD:ddname`, as shown in the following example:

```c
// 'ENVAR("RESOLVER_CONFIG=//DD:TCPDATA")/-d 0')
```

For more information about specifying a ddname, see *z/OS XL C/C++ Programming Guide*. 

This example shows how you can set environment variables using the STDENV DD statement. The environment variables will be read from the location specified by the STDENV DD statement. The advantage of using STDENV is that it eliminates any concern about the maximum number of characters that can be specified on the PARM= parameter of the EXEC JCL statement. Perform the following steps to set environment variables using the STDENV DD statement:

1. Create the MVS data set that will contain the environment variables with a variable length record format (RECFM=V/VB).
   
   This example uses an MVS data set TCPA.ENVAR(OSNMPD).

   **Rule:** Do not use fixed length record format (RECFM=F/FB) to allocate the MVS data set because fixed length pads the environment variables with blanks.

2. Edit the MVS data set so that it contains the environment variables.

   The following example shows setting the RESOLVER_CONFIG environment variable to a file:

   ```c
   RESOLVER_CONFIG=/etc/tcpa.data
   ```

   The following example shows setting the RESOLVER_CONFIG environment variable to an MVS data set:

   ```c
   RESOLVER_CONFIG=\'\'TCPA.MYFILE(TCPDATA)\'
   ```

3. Update the application's JCL to pick up the TCPIP.DATA information from the specified RESOLVER_CONFIG environment variable.

   ```c
   //OSNMPD PROC
   /*
   * Procedure for running the SNMP agent
   */
   //OSNMPD EXEC PGM=EZASNMPD,REGION=4096K,TIME=NOLIMIT,
   // PARM=('POSIX(ON) ALL31(ON)',
   // 'ENVAR("_CEE_ENVFILE=DD:STDENV")/-d 0')
   //STDENV DD DSN=TCPA.ENVAR(OSNMPD),DISP=SHR
   ```

For more information about specifying a list of environment variables using the _CEE_ENVFILE environment variable, see *z/OS XL C/C++ Programming Guide*. 

750 z/OS Communications Server: IP Configuration Guide
Search orders used in the z/OS UNIX environment

This information describes the search orders used in the z/OS UNIX environment for the different file types shown in Table 36 on page 746. The z/OS UNIX socket functions use various types of TCP/IP data sets and files. They include:

- Base resolver configuration files
- Translate tables
- Local host tables
- Protocol information
- Services information
- Host alias table

The particular file or table chosen can be either an MVS data set or z/OS UNIX file, depending on the resolver configuration settings and the presence of given files on the system.

**Note:** A program's first resolver service request initializes the resolver definitions that will be used for all resolver requests. For long running programs, the definitions can be modified by use of the MODIFY REFRESH operator command. For command usage and syntax, see z/OS Communications Server: IP System Administrator's Commands.

Base resolver configuration files

The base resolver configuration file contains TCPIP.DATA statements. In addition to resolver directives, it is referenced to determine, among other things, the data set prefix (DATASETPREFIX statement's value) to be used when trying to access some of the configuration files.

The search order used to access the base resolver configuration file is as follows:

1. GLOBALTCPIPDATA
   - If defined, the resolver GLOBALTCPIPDATA setup statement value is used. For a description of the GLOBALTCPIPDATA statement, see “The resolver and the global TCPIP.DATA file” on page 715.
   - The search continues for an additional configuration file. The search ends with the next file found.
2. The value of the environment variable RESOLVER_CONFIG
   - The value of the environment variable is used. This search will fail if the file does not exist or is allocated exclusively elsewhere.
3. /etc/resolv.conf
4. //SYSTCPD DD card
   - The data set allocated to the ddname SYSTCPD is used. In the z/OS UNIX environment, a child process does not have access to the SYSTCPD DD. This is because the SYSTCPD allocation is not inherited from the parent process over the fork() or exec function calls.
5. userid.TCPIP.DATA
   - *userid* is the user ID that is associated with the current security environment (address space or task/thread)
6. SYS1.TCPPARMS(TCPDATA)
7. DEFAULTTCPIPDATA
   - If defined, the resolver DEFAULTTCPIPDATA setup statement value is used. For a description of the DEFAULTTCPIPDATA statement, see “The resolver and the global TCPIP.DATA file” on page 715.
8. TCPIP.TCPIP.DATA
   - Any TCPIP.DATA statements that have not been found will have their default values, if any, assigned.
Translate tables

The translate tables (EBCDIC-to-ASCII and ASCII-to-EBCDIC) are referenced to determine the translate data sets to be used.

The search order that is used to access this configuration file is as follows. The search order ends at the first file found:

1. The value of the environment variable X_XLATE
   The value of the environment variable is the name of the translate table that is produced by the CONVXLAT TSO command.
2. userid.STANDARD.TCPXLBIN
   userid is the user ID that is associated with the current security environment (address space or task/thread).
3. hlq.STANDARD.TCPXLBIN
   hlq represents the value of the DATASETPREFIX statement that is specified in the base resolver configuration file (if found); otherwise, hlq is TCPIP by default.
4. If no table is found, the resolver uses a hardcoded default table that is identical to the STANDARD member in the SEZATCPX data set.

Tip: You can use a JCL DD statement to preallocate the STANDARD.TCPXLBIN data set and prevent the resolver from dynamically allocating it. The name on the DD statement can be any valid ddname. Preallocation prevents the dynamic allocation messages (for example, IEF237I and IEF285I) from being written to the job output log.

Local host tables

By default, resolver first attempts to use any configured domain name servers for resolution requests. If the resolution request cannot be satisfied, local host tables are used. Resolver behavior is controlled by the following factors:

• TCPIP.DATA statements
  The TCPIP.DATA resolver statements define if and how domain name servers are to be used. The LOOKUP TCPIP.DATA statement can also be used to control how domain name servers and local host tables are used. For more information on TCPIP.DATA statements, see z/OS Communications Server: IP Configuration Reference.

• How your application is written and compiled
  If your application program uses the TCP/IP-provided CC++ API and the XL CC++ RESOLVE_VIA_LOOKUP symbol was defined, only local host tables will be used. For information on the use of the RESOLVE_VIA_LOOKUP symbol, see z/OS Communications Server: IP Sockets Application Programming Interface Guide and Reference and z/OS XL C/C++ Programming Guide.

The local host table supplies sitename information for, as one example, resolving hostnames to host or network addresses. The local host table can also supply address information, for example, for resolving addresses to hostname or network names. There are different search orders used for selecting the local host table for these different purposes. The search order to use is based on certain resolver setup statements, the type of API invocation, and possibly the type of host address (IPv4 versus IPv6) being requested or being resolved.

IPv4-unique search order for sitename information

The resolver uses the IPv4-unique search order for sitename information when the resolver setup statement NOCOMMONSEARCH is specified (or left to default), and either the:

• getaddrinfo API is attempting to locate an IPv4 address.
• gethostbyname, sethostent, gethostent, or endhostent API is invoked.

If the COMMONSEARCH statement is specified, see “IPv6/common search order” on page 753, where the resolver can use IPNODES to locate sitenames.
The resolver uses the IPv4-unique search order for sitename information unconditionally for getnetbyname API calls.

The IPv4-unique search order for sitename information is as follows. The search ends at the first file found:

1. The value of the environment variable X_SITE
   The value of the environment variable is the name of the MVS data set that contains the sitename information. This data set is created by the TSO MAKESITE command.
2. /etc/hosts
3. userid.HOSTS.SITEINFO
   userid is the user ID that is associated with the current security environment (address space or task/thread).
4. hlq.HOSTS.SITEINFO
   hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); otherwise, hlq is TCPIP by default.

IPv4-unique search order for address information

The resolver uses the IPv4-unique search order for address information when the resolver setup statement NOCOMMONSEARCH is specified (or left to default), and either the getnameinfo API is attempting to resolve an IPv4 address or the gethostbyaddr API is invoked. If the COMMONSEARCH statement is specified, see “IPv6/common search order” on page 753, where the resolver can use IPNODES to locate IPv4 and IPv6 addresses.

The resolver uses the IPv4-unique search order for address information unconditionally for the setnetent, getnetent, endnetent, or getnetbyaddr APIs.

The IPv4-unique search order for address information is as follows. The search ends at the first file found:

1. The value of the environment variable X_ADDR
   The value of the environment variable is the name of the MVS data set that contains the address information. This data set is created by the TSO MAKESITE command.
2. /etc/hosts
3. userid.HOSTS.ADDRINFO
   userid is the user ID that is associated with the current security environment (address space or task/thread).
4. hlq.HOSTS.ADDRINFO
   hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); otherwise, hlq is TCPIP by default.

IPv6/common search order

The resolver uses the IPv6/common search order when it determines that any of the following conditions exist:

- The resolver setup statement COMMONSEARCH is specified (to have the resolver use IPNODES to locate IPv4 addresses, IPv6 addresses, and sitenames), and the getaddinfo, gethostbyname, getnameinfo, gethostbyaddr, sethostent, gethostent, or endhostent APIs are invoked.
- The resolver setup statement NOCOMMONSEARCH is specified (or left to default), and the getaddinfo API is attempting to locate an IPv6 address.
- The resolver setup statement NOCOMMONSEARCH is specified (or left to default), and the getnameinfo API is attempting to resolve an IPv6 address.

**Note:** The IPv6/common search order is never used for the following API socket calls:

- getnetbyname
The IPv6/common search order is as follows. The search ends at the first file found:

1. GLOBALIPNODES value
   If defined, the resolver GLOBALIPNODES setup statement value is used. For a description of the
   GLOBALIPNODES statement, see “The resolver setup file” on page 712.
2. The value of the environment variable RESOLVER_IPNODES
3. userid.ETC.IPNODES
   userid is the user ID that is associated with the current security environment (address space or task/
   thread).
4. hlq.ETC.IPNODES
   hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration
   file (if found); otherwise, hlq is TCPIP by default.
5. DEFAULTIPNODES
   If defined, the resolver DEFAULTIPNODES setup statement value is used. For a description of the
   DEFAULTIPNODES statement, see “The resolver setup file” on page 712.
6. /etc/ipnodes

Protocol information
The protocol information supplies protocol related information for the socket calls listed in Table 36 on
page 746.

The search order used to access this configuration file is as follows. The search ends at the first file found:
1. /etc/protocol
2. userid.ETC.PROTO
   userid is the user ID that is associated with the current security environment (address space or task/
   thread).
3. hlq.ETC.PROTO
   hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration
   file (if found); Otherwise, hlq is TCPIP by default.

Services information
The services information supplies the service information for the socket calls listed in Table 36 on page
746.

The search order used to access this configuration file is as follows. The search ends at the first file found:
1. /etc/services
2. userid.ETC.SERVICES
   userid is the user ID that is associated with the current security environment (address space or task/
   thread).
3. hlq.ETC.SERVICES
   hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration
   file (if found); Otherwise, hlq is TCPIP by default.
Host alias table

The host alias table supplies hostname alias information for the socket calls listed in Table 36 on page 746. The format of the alias information is the alias name, followed by a space, followed by the fully qualified domain name that corresponds to the alias name. The domain name is written without a trailing dot, and the alias name cannot contain dots. The search order used to access this configuration file consists only of the value of the environment variable HOSTALIASES.

Search orders used in the native MVS environment

The native MVS environment socket functions use various type of TCP/IP data sets, including:

- Base resolver configuration files
- Translate tables
- Local host tables
- Protocol information
- Services information

The particular file or table chosen depends on the resolver configuration settings and the presence of given files on the system.

**Note:** A program's first resolver service request initializes the resolver definitions that will be used for all resolver requests. For long running programs, the definitions can be modified by use of the MODIFY REFRESH operator command. For command usage and syntax, see z/OS Communications Server: IP System Administrator's Commands.

Base resolver configuration files

The base resolver configuration file contains TCPIP.DATA statements. In addition to resolver directives, it is referenced to determine, among other things, the data set prefix (DATASETPREFIX statement's value) to be used when trying to access some of the configuration files.

The search order used to access the base resolver configuration file is as follows:

1. GLOBALTCPIPDATA.
   - If defined, the resolver GLOBALTCPIPDATA setup statement value is used. For a description of the GLOBALTCPIPDATA statement, see “The resolver and the global TCPIP.DATA file” on page 715.
   - The search continues for an additional configuration file. The search ends with the next file found.
2. //SYSTCPD DD card
   - The data set allocated to the ddname SYSTCPD is used.
   - **Rule:** Because TCPIP.DATA statements might need to be read and used multiple times by the resolver, the FREE=CLOSE JCL parameter should not be used when allocating SYSTCPD. To allow TCPIP.DATA statements to be changed while still allocated for long running programs, consider using a member of an MVS partitioned data set instead of an MVS sequential data set. For these long running applications, the resolver MODIFY REFRESH command should then be used to indicate that TCPIP.DATA statements have been changed.
3. userid/jobname.TCPIP.DATA
   - **userid** is the user ID that is associated with the current security environment (address space or task/thread).
   - **jobname** is the name specified on the JOB JCL statement for batch jobs or the procedure name for a started procedure.
4. SYS1.TCPPARMS(TCPDATA)
5. DEFAULTTCPIPDATA

   - If defined, the resolver DEFAULTTCPIPDATA setup statement value is used. For a description of the DEFAULTTCPIPDATA statement, see “The resolver and the global TCPIP.DATA file” on page 715.
6. TCPIP.TCPIP.DATA

Translate tables
The translate tables are referenced to determine the translate data sets to be used.

The search order that is used to access this configuration file is as follows. The search order ends at the first file found:

1. userid/jobname.STANDARD.TCPXLBIN
   - userid is the user ID that is associated with the current security environment (address space or task/thread).
   - jobname is the name that is specified on the JOB JCL statement for batch jobs or the procedure name for a started procedure.

2. hlq.STANDARD.TCPXLBIN
   - hlq represents the value of the DATASETPREFIX statement that is specified in the base resolver configuration file (if found); otherwise, hlq is TCPIP by default.

3. If no table is found, the resolver uses a hardcoded default table that is identical to the STANDARD member in the SEZATCPX data set.

Tip: You can use a JCL DD statement to preallocate the STANDARD.TCPXLBIN data set and prevent the resolver from dynamically allocating it. The name on the DD statement can be any valid ddname. Preallocation prevents the dynamic allocation messages (for example, IEF237I and IEF285I) from being written to the job output log.

Local host tables
By default, resolver first attempts to use any configured domain name servers for resolution requests. If the resolution request cannot be satisfied, local host tables are used. Resolver behavior is controlled by the following factors:

- TCPIP.DATA statements
  - The TCPIP.DATA resolver statements define if and how domain name servers are to be used. The LOOKUP TCPIP.DATA statement can also be used to control how domain name servers and local host tables are used. For more information on TCPIP.DATA statements, see z/OS Communications Server: IP Configuration Reference.
  - How your application is written and compiled
    - If your application program uses the TCP/IP-provided C/C++ API and the RESOLVE_VIA_LOOKUP symbol was defined, only local host tables will be used. For information on the use of the RESOLVE_VIA_LOOKUP symbol, see z/OS Communications Server: IP Sockets Application Programming Interface Guide and Reference.

The local host table supplies sitename information for, as one example, resolving hostnames to host or network addresses. The local host table can also supply address information, for example, for resolving addresses to hostname or network names. There are different search orders used for selecting the local host table for these different purposes. The search order to use is based on certain resolver setup statements, the type of API invocation, and possibly the type of host address (IPv4 versus IPv6) being requested or being resolved.

IPv4-unique search order for sitename information
The resolver uses the IPv4-unique search order for sitename information when the resolver setup statement NOCOMMONSEARCH is specified (or left to default), and either the:

- getaddrinfo API is attempting to locate an IPv4 address.
- gethostbyname, GetHostNumber, GetHostResol, IsLocalHost, Resolve, sethostent, gethostent, or endhostent API is invoked.
If the COMMONSEARCH statement is specified, see “IPv6/common search order” on page 757, where the resolver can use IPNODES to locate sitenames.

The resolver uses the IPv4-unique search order for sitename information unconditionally for getnetbyname API calls.

The IPv4-unique search order for sitename information is as follows. The search ends at the first file found:

1. userid/jobname.HOSTS.SITEINFO
   - userid is the user ID that is associated with the current security environment (address space or task/thread).
   - jobname is the name specified on the JOB JCL statement for batch jobs or the procedure name for a started procedure.
2. hlq.HOSTS.SITEINFO
   - hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); otherwise, hlq is TCPIP by default.

**IPv4-unique search order for address information**

The resolver uses the IPv4-unique search order for address information when the resolver setup statement NOCOMMONSEARCH is specified (or left to default), and either the getnameinfo API is attempting to resolve an IPv4 address or the gethostbyaddr or GetHostString API is invoked. If the COMMONSEARCH statement is specified, see “IPv6/common search order” on page 757, where the resolver can use IPNODES to locate IPv4 and IPv6 addresses.

The resolver uses the IPv4-unique search order for address information unconditionally for the setnetent, getnetent, endnetent, or getnetbyaddr APIs.

The IPv4-unique search order for address information is as follows. The search ends at the first file found:

1. userid/jobname.HOSTS.ADDRINFO
   - userid is the user ID that is associated with the current security environment (address space or task/thread).
   - jobname is the name specified on the JOB JCL statement for batch jobs or the procedure name for a started procedure.
2. hlq.HOSTS.ADDRINFO
   - hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); otherwise, hlq is TCPIP by default.

**IPv6/common search order**

The resolver uses the IPv6/common search order when it determines that any of the following conditions exist:

- The resolver setup statement COMMONSEARCH is specified (to have the resolver use IPNODES to locate IPv4 addresses, IPv6 addresses, and sitenames), and the getaddrinfo, gethostbyname, getnameinfo, gethostbyaddr, GetHostNumber, GetHostResol, GetHostString, IsLocalHost, Resolve, sethostent, gethostent, or endhostent APIs are invoked.
- The resolver setup statement NOCOMMONSEARCH is specified (or left to default), and the getaddrinfo API is attempting to locate an IPv6 address.
- The resolver setup statement NOCOMMONSEARCH is specified (or left to default), and the getnameinfo or Resolve API is attempting to resolve an IPv6 address.

**Note:** The IPv6/common search order is never used for the following API socket calls:

- getnetbyname
- getnetbyaddr
• setnetent
• getnetent
• endnetent

The IPv6/common search order is as follows. The search ends at the first file found:

1. GLOBALIPNODES value
   If defined, the resolver GLOBALIPNODES setup statement value is used. For a description of the
   GLOBALIPNODES statement, see “The resolver setup file” on page 712.

2. userid/jobname.ETC.IPNODES
   
   userid is the user ID that is associated with the current security environment (address space or task/
   thread).
   
   jobname is the name specified on the JOB JCL statement for batch jobs or the procedure name for a
   started procedure.

3. hlq.ETC.IPNODES
   hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration
   file (if found); otherwise, hlq is TCPIP by default.

4. DEFAULTIPNODES
   If defined, the resolver DEFAULTIPNODES setup statement value is used. For a description of the
   DEFAULTIPNODES statement, see “The resolver setup file” on page 712.

5. /etc/ippnodes

Protocol information

The protocol information supplies protocol related information for the socket calls listed in Table 36 on
page 746.

The search order used to access this configuration file is as follows. The search ends at the first file found:

1. userid/jobname.ETC.PROTO
   userid is the user ID that is associated with the current security environment (address space or task/
   thread).
   
   jobname is the name specified on the JOB JCL statement for batch jobs or the procedure name for a
   started procedure.

2. hlq.ETC.PROTO
   hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration
   file (if found); Otherwise, hlq is TCPIP by default.

Services information

The services information supplies service information for the socket calls listed in Table 36 on page 746.

The search order used to access this configuration file is as follows. The search ends at the first file found:

1. //SERVICES DD card
   The data set allocated to the ddname SERVICES is used.

2. userid/jobname.ETC.SERVICES
   userid is the user ID that is associated with the current security environment (address space or task/
   thread).
   
   jobname is the name specified on the JOB JCL statement for batch jobs or the procedure name for a
   started procedure.

3. hlq.ETC.SERVICES
hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); Otherwise, hlq is TCPIP by default.
Chapter 14. Policy-based networking

Businesses typically define goals for network behavior in human terms. Network implementations provide a variety of application-transparent controls for priority treatment of traffic, bandwidth management, security, and control of network behavior. The link between the high-level business goals and network implementations is defined as policy-based networking and is provided by policies. Policies are usually defined in a centralized repository and are accessed by nodes that need to make policy decisions (Policy Decision Point, or PDP) or implement such decisions (Policy Enforcement Point, or PEP).

Policy types and infrastructure overview

To implement networking policies for your users, you must use the z/OS Communications Server policy infrastructure. You can use the policy types supported by the Policy Agent for any of the following purposes:

- Policy-based routing (See “Policy-based routing” on page 335)
- Quality of service (See Chapter 15, “Quality of service,” on page 803)
- Intrusion detection services (See Chapter 16, “Intrusion detection services,” on page 823)
- IP filtering, and manual and dynamic virtual private network (VPN) tunnels, collectively referred to as IPSec policies (See Chapter 17, “IP security,” on page 855)
- Application Transparent Transport Layer Security (AT-TLS, see Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1093)

For more information about the policy types, see “Policy types” on page 774.

Based on the policy types that you want to implement, you must configure and start one or more policy infrastructure components:

- TCP/IP stack
  TCP/IP stacks implement most of the policy types. You need to start one or more stacks per logical partition (LPAR).
- Syslog daemon (syslogd)
  Syslogd acts as the central message logging facility for z/OS UNIX applications. Syslogd is not specific to the policy infrastructure, but the policy infrastructure depends on syslogd to provide a central logging facility to maintain an audit trail. If you do not start syslogd, messages are lost. You should start one syslog daemon per LPAR.
- Policy Agent
  You must start Policy Agent to install and maintain policies in the TCP/IP stacks in an LPAR. You need one Policy Agent per LPAR.
- Traffic regulation management daemon (TRMD)
  TRMD formats and sends policy-related messages to your syslog daemon. You need one TRMD per TCP/IP stack in an LPAR.
- Internet Key Exchange daemon (IKED)
  IKED is used for negotiating and setting up dynamic VPN tunnels. If you are not using dynamic VPN tunnels, you do not need to start IKED; otherwise, you need one IKED per LPAR.
- Network security services daemon (NSSD)
  NSSD can be used as the central certificate and key server for z/OS IKE daemons, or as a network security server for selected non-z/OS platforms. NSSD can be used independently of any z/OS networking policies, but is an element of the overall z/OS networking policy infrastructure. Typically, you do not need an NSSD on every LPAR; one NSSD per sysplex is more likely.
• Defense Manager daemon (DMD)
  DMD provides support for short-term defensive filters. You can use DMD without defining any IPSec filter policies, but typically you use DMD in addition to IPSec filter policy. You need one DMD per LPAR.
• Network service level agreement performance monitor 2 (NSLAPM2)
  NSLAPM2 is an SNMP subagent that provides QoS metrics through MIB variables. You need one NSLAPM2 per TCP/IP stack in an LPAR.

For more information about syslogd, see “Configuring the syslog daemon” on page 199. For more information about the other policy infrastructure components, see “Policy infrastructure components” on page 767.

To determine the policy infrastructure components that you need to start based on which policy types you are implementing, see Table 37 on page 762.

<table>
<thead>
<tr>
<th>Policy type</th>
<th>Component</th>
</tr>
</thead>
<tbody>
<tr>
<td>TCP/IP stack</td>
<td>Policy Agent, syslogd, IKED, NSSD, DMD, NSLAPM2, TRMD</td>

</tbody>
</table>

You can use the IBM Configuration Assistant for z/OS Communications Server for assistance with setting up and configuring security, JCL procedures, and configuration files for the following policy infrastructure components:
• Policy Agent, including policy definition files for QoS, IDS, AT-TLS, IPSec, and policy-based routing
• IKED
• NSSD
• DMD
To operate correctly, the policy infrastructure depends on various configuration files and policy definitions files.

The IBM Configuration Assistant for z/OS Communications Server enables flat-file configuration of all supported policy types for z/OS. The IBM Configuration Assistant for z/OS Communications Server is an optional GUI-based tool that provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the IBM Configuration Assistant for z/OS Communications Server to generate the Policy Agent files.

The IBM Configuration Assistant for z/OS Communications Server is a z/OS Management Facility (z/OSMF) task. z/OSMF provides a web browser interface for a variety of z/OS system management functions. When you invoke the IBM Configuration Assistant for z/OS Communications Server in z/OSMF, the IBM Configuration Assistant for z/OS Communications Server runs natively in the z/OS system and you can access it through a web browser.

Table 38 on page 763 lists the policy-related configuration and definition files, whether the files can be created using the IBM Configuration Assistant for z/OS Communications Server, and the default location of the configuration files. You can manually edit all files listed in Table 38 on page 763.

### Table 38. Configuration files and policy definition files

**Managing changes to configuration files and policy definition files**

Typically, you use a change management procedure when you install a set of new or changed policies, or when you modify the configuration files for the Policy Agent or other policy-related applications. A structure for storing and maintaining the configuration files and policy definition files that are related to the general policy infrastructure is provided by the IBM Configuration Assistant for z/OS Communications Server, and you can use it to manually create and edit the configuration files and policy definition files. The structure is based on three location levels:

- Staging
The staging level is the location in which you manually edit your definitions, or into which you upload definitions from the IBM Configuration Assistant for z/OS Communications Server.

- **Production**
  The production level is the location to which you copy your staging definitions when you are ready to put your changes into production. This is the location from which your Policy Agent and other policy infrastructure components read their definitions.

- **Backup and recovery**
  The backup and recovery level is the location to which you copy your existing production definitions before you copy your staging definitions to your production location. If the changes are in error, you can back out the changes by copying your original production definitions from the recovery location to the production location and restarting your policy infrastructure components.

### Storing configuration files and policy definition files

You can store configuration files and policy definition files in the z/OS UNIX file system or in traditional MVS data sets.

Some definitions are shared by all TCP/IP stacks on a z/OS image, and some definitions are specific to individual TCP/IP stacks on a z/OS image.

For example, if you are using the z/OS UNIX file system to store your configuration files and policy definition files, a directory structure for z/OS image SYSA with TCP/IP stacks TCPIP1 and TCPIP2 might look as follows:

- **Staging**
  - **Image-wide**
    /etc/tcpip/POLTRANS/SYSA/
  - **TCPIP1**
    /etc/tcpip/POLTRANS/SYSA/TCPIP1/
  - **TCPIP2**
    /etc/tcpip/POLTRANS/SYSA/TCPIP2/

- **Production**
  - **Image-wide**
    /etc/tcpip/POLPROD/SYSA/
  - **TCPIP1**
    /etc/tcpip/POLPROD/SYSA/TCPIP1/
  - **TCPIP2**
    /etc/tcpip/POLPROD/SYSA/TCPIP2/

- **Backup and recovery**
  - **Image-wide**
    /etc/tcpip/POLBACK/SYSA/
  - **TCPIP1**
    /etc/tcpip/POLBACK/SYSA/TCPIP1/
  - **TCPIP2**
    /etc/tcpip/POLBACK/SYSA/TCPIP2/

Similarly, you can use MVS partitioned data set (PDS) or partitioned data set extended (PDSE) libraries to store the configuration files and policy definition files as follows:

- **Staging**
  - **Image-wide**
    hlx.TCPPARMS.POLTRANS.SYSA
  - **TCPIP1**
    hlx.TCPPARMS.POLTRANS.SYSA.TCPIP1
You can maintain a number of members in each of these libraries, using your own naming convention or the following suggested naming convention:

- **LPAR-wide configuration files**
  - CONF (configuration file)
- **Stack-specific configuration and policy definition files**
  - TLSPOL (AT-TLS policy definitions)
  - IDSPOL (IDS policy definitions)
  - IPSPOL (IPSec policy definitions)
  - QOSPOL (QoS policy definitions)
  - PBRPOL (Policy-based routing policy definitions)

The following example shows the IKE daemon configuration file and the IPSec policy definitions for stack TCPIP1 as members of PDS or PDSE libraries:

```
USER.LPAR1.POLTRANS.SYSA.IKED(CONF)
USER.LPAR1.POLTRANS.SYSA.TCPIP1(IPSPOL)
```

### Steps for managing policy changes

Place your new policy flat file in the staging library, back up your current production policy flat file, and then replace the production copy with the new copy.

### Procedure

As shown in Figure 100 on page 766, perform the following steps to activate changes to your policies:

1. Transfer the policy flat file to the staging library. *hlq.TCPPARMS.POLTRANS.SYSA.TCPIP1(xyz)*
2. Back up the current production policy flat file.
   
   Copy *hlq.TCPPARMS.POLPROD.SYSA.TCPIP1(xyz)* to *hlq.TCPPARMS.POLBACK.SYSA.TCPIP1(xyz)*
3. Copy the new policy flat file into production.
   
   Copy *hlq.TCPPARMS.POLTRANS.SYSA.TCPIP1(xyz)* to *hlq.TCPPARMS.POLPROD.SYSA.TCPIP1(xyz)*

### Results
Policy Agent reads the definitions from the production location, as shown by step 4 in Figure 100 on page 766.

Tips:

- If the changes you make are in error, you can back out the changes by copying your original production definitions from the recovery location to the production location and restarting your policy infrastructure components.

- In your procedure to move objects from POLTRANS to POLPROD, you might have to include a utility step to change location references from POLTRANS to POLPROD.

  Some configuration files might include references to other configuration file locations or policy definition file locations. Those locations are initially the POLTRANS location.

- You can override names suggested by the IBM Configuration Assistant for z/OS Communications Server and choose to use other names.

  If you are using the IBM Configuration Assistant for z/OS Communications Server, you are prompted for the base location for a z/OS image. For each configuration file, policy definition file, sample RACF job, sample JCL procedure, and so on, the IBM Configuration Assistant for z/OS Communications Server suggests a name to serve as the file name in the z/OS UNIX file system directories, or as the member name in the PDS or PDSE libraries.

- Specifying an EBCDIC code page that matches your default country settings makes it easier to browse the files with ISPF.

  Most policy-related configuration files and all the policy definition files support an optional Codepage parameter that you can use to indicate the EBCDIC code page in which the contents are encoded. When you use the IBM Configuration Assistant for z/OS Communications Server, you specify the EBCDIC code page when you define the base location for a z/OS image. The IBM Configuration Assistant for z/OS Communications Server transfers configuration files and policy definitions files to that z/OS image using the specified code page and includes the Codepage option in the files. The following example shows the initial section of a Policy Agent configuration file that uses the Codepage option:

```powershell
## Configuration Assistant, 2008.11.25 09:33:12
## Pagent Configuration for system MVS98
## Target Codepage = IBM-278
TcpImage TCPCS 'USER1.TCPPARMS.MVS98.TCPCS(STKPAG)' FLUSH NOPURGE 360
Codepage IBM-278
## Loglevel 127       ## default 31
```
Policy infrastructure components

Based on the policy types that you want to implement, you must configure and start one or more policy infrastructure components.

For more information about syslogd, see “Configuring the syslog daemon” on page 199.

TCP/IP stack

Most policy types are implemented by the TCP/IP stack. IPSec dynamic VPNs are implemented by the IKE daemon.

As packets are sent or received, they are matched against policies of the appropriate type as needed. In general, policy processing occurs at the following layers in the stack:

- Application layer - AT-TLS
- IP layer - IPSec filtering and policy-based routing
- Transport layer - IDS and QoS

Some types of IDS checks are also performed at the IP layer in the stack.

When a matching policy is found, it is implemented against the packet. Depending on the policy type and packet contents, this results in a wide variety of actions. For example, the packet might be discarded, processed according to its priority, or have its routing changed. For information about the policy action statements and the kinds of processing that can be applied for each policy type, see the Policy Agent and policy applications information in z/OS Communications Server: IP Configuration Reference.

Policy Agent

Policy Agent can act in any of several roles, and provides various services, such as managing dependent components of the policy infrastructure.

The term Policy Agent refers to any roles or services provided by Policy Agent. The terms policy server and policy client refer to those specific roles, and the term import requester refers to the configuration file import service.

Policy Agent roles

The Policy Agent runs in the z/OS environment and can act in any of several roles, depending on configuration options:

- The Policy Agent can act as a self-contained Policy Decision Point (PDP) on a single system, installing policies in one or more z/OS Communications Server stacks on that z/OS image, as shown by system SYSA in Figure 101 on page 768.
- The Policy Agent can act as a policy client, retrieving remote policies from the policy server, as shown by system SYSB in Figure 101 on page 768. Each stack in a Common INET (CINET) environment that is configured to the Policy Agent acts as a separate policy client.
- The Policy Agent can act as a centralized policy server, providing PDP services for one or more remote policy clients, as shown by system SYSC in Figure 101 on page 768.
- A single Policy Agent can act as a policy client or a policy server, but not both.
Policy Agent services

Policy Agent provides the following services:

- Reads and parses policy definitions, and provides those policies to one or more TCP/IP stacks or policy clients. The Policy Agent actively participates in maintaining the policies by monitoring the policy files, detecting changes, and informing the TCP/IP stacks or policy clients about any changes.

- Imports policy through a passive service known as policy file import. The main user of this service is the IBM Configuration Assistant for z/OS Communications Server, through its Policy Data Import function. For this configuration file import service, the Policy Agent reads and parses policy definitions one time, and provides the policies to an import requester. The import requester can import the policies into an existing configuration, or can just verify that the policy definitions are without errors.

- Imports TCP/IP profile information through a passive service known as the discovery of TCP/IP profile function. The main user of this service is the IBM Configuration Assistant for z/OS Communications Server. For this request, the Policy Agent retrieves information from the TCP/IP profile. The import requester can retrieve this information and use it as configuration data.

- Starts, monitors, stops, and restarts dependent components of the policy infrastructure. You can instruct Policy Agent to manage the following components:
  - DMD
  - IKED
Policy Agent policies

Policies can be defined in several different ways.

Table 39 on page 769 shows the format you can use for different policy types.

<table>
<thead>
<tr>
<th>Policy type</th>
<th>Text file format ¹</th>
<th>LDAP format ²</th>
</tr>
</thead>
<tbody>

<tr>
<td>AT-TLS</td>
<td>Yes</td>
<td>No</td>
</tr>
<tr>
<td>IPSec</td>
<td>Yes</td>
<td>No</td>
</tr>
<tr>
<td>Policy-based routing</td>
<td>Yes</td>
<td>No</td>
</tr>
</tbody>
</table>

¹ The IBM Configuration Assistant for z/OS Communications Server builds policy definitions only in text file format.

² The format of the LDAP schema for IDS and QoS policies was stabilized in z/OS V1R2. Only IDS and QoS policies supported by that release are supported when you are using an LDAP server to store IDS and QoS policies. For information about defining policies on an LDAP server, see Appendix F, “Using an LDAP server for policy definitions,” on page 1347.

When acting as the Policy Decision Point (PDP) for a single system, Policy Agent can read policy definitions from local configuration files, a central repository that uses the Lightweight Directory Access Protocol (LDAP), or both. The Policy Agent also installs policies in one or more z/OS Communications Server stacks. It can be used to replace existing policies or to update them as necessary.

When acting as a policy server, Policy Agent also acts as a PDP for the local system, and thus can read policies from local configuration files or an LDAP server and install them in local stacks. However, it also reads policies from local configuration files on behalf of policy clients. These policies are retrieved by policy clients, but are not installed in the local stacks on the policy server.

Restriction: Dynamic monitoring for file updates using the -i startup option is not supported for files read on behalf of policy clients.

When acting as a policy client, Policy Agent retrieves remote policies from the policy server, and can also use local policies from configuration files or an LDAP server. The choice of local or remote policies can be made separately for each supported policy type (QoS, IDS, IPSec, Routing, or AT-TLS). The policy client informs the policy server of its local capabilities, so that the policy server can perform appropriate parsing of the policies. For example, the policy client might not support the IPSec 3DES encryption algorithm, so the policy server needs to fail IPSec policies that specify 3DES, even if the policy server itself does support 3DES.

If the policy client and policy server are at different release levels, you must be careful when defining policies on the policy server.

• If the policy client is at a higher release level than that of the policy server, you can define policies using the syntax and semantics of only the lower-level policy server. You cannot use the capabilities that exist only in the higher release level, such as new statements, parameters, or parameter values. Error checking might also be unavailable for use; rules or restrictions might be added to or removed from the higher release level.
• If the policy server is at a higher release level than that of the policy client, you cannot define policies using syntax and semantics that are available only in the higher release level. The policy server cannot parse such policies on behalf of a policy client at a lower release level, so the policies are reported as containing errors.

• If the policy server is at a lower release level than that of the policy client, any policies using syntax and semantics that were removed from the higher release level are still parsed and returned from the policy server to the policy client.

As a general rule, configure policies based on the target system, not on the system where the policies are defined.

For a table of statements, parameters, parameter values, and rules or restrictions that are valid only for certain release levels, see z/OS Communications Server: IP Configuration Reference.

The policy client can be configured with a backup as well as a primary policy server. The policy client continually tries the connection to the primary policy server (and the connection to the backup if a backup is configured) using the connection retry values configured on the ServerConnection statement, until a connection is successfully established.

For more information, see the following topics:

• “Policy-based routing” on page 335
• Chapter 15, “Quality of service,” on page 803
• Chapter 16, “Intrusion detection services,” on page 823
• Chapter 17, “IP security,” on page 855
• Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1093

Restriction: You cannot define AT-TLS policies, IPSec policies, or routing policies on LDAP servers.

Tip: Policies defined on an LDAP server use the configuration files and mechanisms provided by the LDAP server product. The definition of the elements of policies is known as the schema. z/OS Communications Server provides the schema definition for policies that may be defined on an LDAP server in a set of sample files. The sample files are provided in LDAP protocol version 3 format (see “LDAP sample files” on page 1037 for the names of these samples). These sample files must be installed on the LDAP server as the schema definition. Policy Agent uses the z/OS Integrated Security Server LDAP Client library to communicate with an LDAP server. See z/OS IBM Tivoli Directory Server Administration and Use for z/OS for more information about LDAP. A copy of the LDAP definition files that define the policy definitions for LDAP is available in z/OS Communications Server: IP Configuration Reference.

Local policies are defined in Policy Agent configuration files, in the LDAP server, or both. Remote policies are defined in Policy Agent configuration files on the policy server. Policies from configuration files and the LDAP server are combined into a single list. This requires unique policy object names per type (QoS, IDS, IPSec, Routing, and AT-TLS). On a policy client, policies for a given type are retrieved either locally or remotely, but not both.

For policies defined on the LDAP server, the distinguished name (DN) must be unique, but the user-friendly name does not have to be unique (although it should be). The Policy Agent appends a unique suffix if it is required to make LDAP user-friendly names unique within the scope of policies defined on the LDAP server. When policies from a configuration file are combined with LDAP-defined policies, the LDAP user-friendly names must be unique with respect to the names defined in the configuration file. Any policy objects of the same type (that is, QoS or IDS) with duplicate names at this point are discarded by the Policy Agent and an error is reported.

Configuration file import services

The IBM Configuration Assistant for z/OS Communications Server can request that existing policy configuration files or TCP/IP profile information be imported for further changes and additions. When the Policy Agent provides this configuration file import service, the IBM Configuration Assistant for z/OS Communications Server is acting as an import requester. These policy files are import configuration files and the resulting policies are import policies. When the IBM Configuration Assistant for z/OS Communications Server is acting as an import requester, the required input values are configured on its
Import Policy Data panel or on request panels for discovery import (for example, the Discover Stack Local Addresses panel):

- Host connection IP address and port for the Policy Agent
- Host connection user name and password to identify resources that this user can access
- Indication of whether a secure connection (SSL) should be used, by configuring your own AT-TLS policies or by having the Policy Agent install generated AT-TLS policies.

You configure the type of security for a connection (basic or secure) on the ServicesConnection statement for the Policy Agent. The type can be either basic or secure. For more details, see “Step 6: Configure Policy Agent for configuration file import services” on page 790.

- Import Policy Data panel only:
  - Policy type to identify what type of policies to import
  - Optional policy configuration file names (common file, stack-specific file, or both)
  - Import request name to identify the stack name

The import request name, user name, and policy type are used to identify resources this user can access.

If no import configuration files are passed, the import request name is used to match an existing TcpImage or PEPInstance statement to find the import configuration file names for the input policy type.

Restrictions:

- The import requester's port value must be the same as the port value defined on the ServicesConnection statement.
- The import requester's type of security (SSL or not) must match the type of security configured on the ServicesConnection statement (secure or basic).
  - For the secure type, it must match the Policy Agent generated AT-TLS policies.
  - For the basic type, you can either use a default unsecure connection or explicitly define AT-TLS policies to protect the connection.

- Import policies only:
  - The import configuration files are parsed only once. The import policies are not installed in the TCP/IP stack, so the FLUSH and PURGE parameters and the MODIFY REFRESH and MODIFY UPDATE commands do not apply to these files. These files are not monitored for changes.
  - You can define import policies only in configuration files. You cannot define them on an LDAP server.
  - The import request name, user name, and policy type are required for security product authorization in the SERVAUTH class. For authorization details, see “Step 1: Configure general information” on page 780.

For detailed configuration information, see “Step 6: Configure Policy Agent for configuration file import services” on page 790.

Additional QoS services

The Policy Agent supports QoS functions other than reading and installing policies, such as syslog distributor policy performance monitoring, and mapping IPv4 Type of Service (ToS) byte or IPv6 Traffic Class values to outbound interface and virtual LAN (VLAN) user priorities. The QoS specific Policy Agent functions are further described in “QoS-specific Policy Agent functions” on page 805.

Policy API

A Policy API (PAPI) is provided to allow access to policy information by external user applications. The PAPI interface can be used by policy performance monitoring applications to retrieve policy performance data. For more information on PAPI, see z/OS Communications Server: IP Programmer's Guide and Reference.
Traffic regulation management daemon

Intrusion detection services (IDS) support is available to detect and report on network intrusion events. The Traffic Regulation Management (TRM) support has been extended and incorporated into the IDS support. IDS policy regulates the types of events to report and provides the definition of several types of events. IDS policy may be defined for scans, attacks and traffic regulation for both TCP and UDP ports.

IKE daemon

IPSec services include IP filtering and support for manual and dynamic VPN tunnels. The Internet Key Exchange (IKE) daemon works with the stack to provide IPSec support. IPSec policy can be defined for IP filtering (including manual VPN tunnels), key exchange, and dynamic VPN tunnels.

Network security services daemon

A network security services daemon (NSSD) provides network security services for one or more security disciplines, including IPSec. For the IPSec discipline, these services include the IPSec certificate service and the IPSec remote management service. For more information, see Chapter 18, “Network security services,” on page 1055.

Tip: You do not define policies for NSSD.

Defense Manager daemon

The Defense Manager daemon (DMD) provides defensive filters, which are IP filter rules to discard packets that are separate from IP security filters, and which are typically installed for a short duration (for example, 30 minutes) to block a specific attack or a pattern of attacks. For more information, see Chapter 19, “Defensive filtering,” on page 1079.

Tip: You do not define policies for DMD.

SNMP Network SLAPM2 subagent

The z/OS CS Network SLAPM2 subagent (nslapm2) allows network administrators to retrieve data and determine if the current set of Network SLAPM2 policy definitions are performing as needed or if adjustments need to be made. The Network SLAPM2 subagent supports the Network Service Level Agreement Performance Monitor (NETWORK-SLAPM2) MIB. See usr/lpp/tcpip/samples/slapm2.mi2 for more information about the Network SLAPM2 MIB.

Sample policy infrastructure

Figure 102 on page 773 shows the Policy Agent in a sample policy infrastructure.
The IBM Configuration Assistant for z/OS Communications Server performs the following functions:

- GUI to build the configuration flat-files for IPSec, AT-TLS, IDS, Routing, and QoS policies.
- Import requester to request configuration file import services from the Policy Agent. For details, see “Configuration file import services” on page 770.

**Policy sample files**

A set of sample files is shipped with z/OS CS that provides several functions. The first sample file provides an example of policy definitions in a Policy Agent configuration file.

**/usr/lpp/tcpip/samples/pagent.conf**

This file contains overall policy definition rules, syntax and semantics for defining policies in a configuration file, and examples of such policy definitions.

The next set of sample files provide sample IPSec policy definitions.

**/usr/lpp/tcpip/samples/pagent_CommonIPSec.conf**

This file contains sample common IPSec policy definitions. These can be referenced and reused by multiple stack-specific IPSec configuration files.

**/usr/lpp/tcpip/samples/pagent_IPSec.conf**

This file contains sample stack-specific IPSec policy definitions. Some of these refer to common definitions in /usr/lpp/tcpip/samples/pagent_CommonIPSec.conf.

The following file provides sample AT-TLS policy definitions.
This file contains sample AT-TLS policy definitions. These definitions can either be in a common or stack-specific AT-TLS file. If these definitions are in a common AT-TLS file, they can be referenced and reused by multiple stack-specific AT-TLS configuration files. If these definitions are in a stack-specific AT-TLS file, they are used only by that specific stack.

The following file provides sample IDS policy definitions.

This file contains sample IDS policy definitions. These definitions can either be in a common or stack-specific IDS file. If these definitions are in a common IDS file, they can be referenced and reused by multiple stack-specific IDS configuration files. If these definitions are in a stack-specific IDS file, they are used only by that specific stack.

The following file provides sample policy-based routing policy definitions.

This file contains sample policy-based routing policy definitions. These definitions can either be in a common or stack-specific routing file. If these definitions are in a common routing file, they can be referenced and reused by multiple stack-specific routing configuration files. If these definitions are in a stack-specific routing file, they are used by only that specific stack.

The following files include sample C applications that can be used to develop policy performance monitoring applications.

This file contains instructions for compiling and running the following sample C applications.

This file is a sample C application (pCollector) that uses the Policy API (PAPI) interfaces to access policy performance data. It can be used as the base for an application that provides near real-time policy performance monitoring.

This file is a header file for the pCollector sample application.

This file is a sample C application (pLogReader) that reads the policy performance log file to access policy performance data. It can be used as the base for an application that provides offline policy performance monitoring.

This documentation refers to Version 1 through Version 4 when defining policies.

• Version 1 refers to policy definitions defined with the ServicePolicyRules and ServiceCategories statements or LDAP objects.
• Version 2 through Version 4 refer to policy definitions defined with other policy statements or LDAP objects.
• The primary difference between Version 2 and Version 3 is in the definition of the LDAP schema.
• Version 4 is used with configuration file IDS and Routing policies.

For information about LDAP samples and schema definition files, see Appendix F, “Using an LDAP server for policy definitions,” on page 1347.

Policy types

The Policy Agent supports the following types of policies. Each policy type is referred to as a discipline.

• Quality of service (QoS) policies
  – Differentiated Services (DS) policies
  – Integrated Services (RSVP) policies
  – Sysplex distributor (SD) policies
• Intrusion detection services (IDS) policies
  – Scan policies
  – Attack policies
  – Traffic Regulation policies
• IP security (IPSec) policies
  – IP filtering policies
  – Key exchange policies
  – Local dynamic VPN policies
• Application Transparent Transport Layer Security (AT-TLS) policies
• Policy-based routing (Routing) policies

For information about how IPv6 affects the Policy Agent and which types of policies support IPv6, see z/OS Communications Server: IPv6 Network and Application Design Guide.

These policy types are defined using different policy schemas. They use a common rule, but have separate conditions and actions. None of the different policy types can be mixed in a given policy object. All policy rules can contain time-related information that indicates when the policy rule should be considered active or inactive.

For the QoS, IDS, Routing, and AT-TLS types, active policy rules are installed in the TCP/IP stack, so they can be applied as traffic filters, while inactive policy rules exist only in the Policy Agent. For the IPSec type, both active and inactive IP filtering policies are installed in the TCP/IP stack. However, only manual VPN tunnels that are active as a result of a time condition are installed in the stack. For the Routing policy type, active route tables are installed in the stack, while inactive route tables exist only in the Policy Agent. Configured route tables are active when they are referenced by an active Routing rule and its associated Routing action.

The Policy Agent supports all of the previously mentioned policy types, installing them into one or more TCP/IP stacks as configured. However, policies to be retrieved by policy clients are not installed in any stacks on the policy server.

QoS policy

Policy conditions consist of a variety of selection criteria that act as traffic filters. Traffic can be filtered based on source and destination IP addresses, source and destination ports, protocol, inbound and outbound interfaces, application name, application specific data or application priority. Only packets that match the filter criteria are selected to receive the accompanying action. Policy rules can refer to several policy actions, but only one policy action is executed per policy scope. A given policy action may be referred to by several policy rules.

The type of policy defined is in general controlled by the policy scope value defined for the policy action. SD policies are an exception. SD policies are a subset of DS policies, so use the DS scope.

Although RSVP policies are installed into the TCP/IP stack, they are used only for collecting policy statistics. For policy use and limit enforcement, these policies are requested from the Policy Agent by the RSVP Agent, to apply to RSVP reservation requests from RSVP applications.

IDS policy

Policy conditions primarily determine the portion of IDS function that is being configured. A given IDS policy rule refers to a single IDS policy action. A given IDS policy action may be referred to by several policy rules of the same IDS type. See Chapter 16, “Intrusion detection services,” on page 823 for more details.

IPSec policy

Policy conditions consist of a variety of selection criteria that act as filters for IP filtering rules. Traffic can be filtered based on source and destination IP addresses, source and destination ports, protocol,
direction, routing information, and security class. For other types of IPSec policies, policy conditions contain information about dynamic key exchange filters or dynamic VPN tunnels. For more details, see Chapter 17, “IP security,” on page 855.

IP filter rules and key exchange rules can refer to one or more policy conditions. A policy rule with a single policy condition is known as a simple rule, while one with more conditions is known as a complex rule. Complex IP filter rules and key exchange rules have their conditions evaluated according to Conjunctive Normal Form (CNF), which means an ANDed set of ORed conditions. For details on CNF, see “Policy object model overview” on page 1347.

Complex IP filter rules (rules that contain groupings, or sets, of individual conditions) are split to produce multiple simple rules to be installed in the TCP/IP stack. The conditions in the IpFilterRule statement that can make a filter rule complex are:

- **IpSourceAddr**
  If multiple source addresses (or address ranges) are specified in a rule, the rule is considered complex. Multiple source addresses can be specified by referencing a set or group of addresses from the rule (IpSourceAddrGroupRef).

- **IpDestAddr**
  If multiple destination addresses (or address ranges) are specified in a rule, the rule is considered complex. Multiple destination addresses can be specified by referencing a set or group of addresses from the rule (IpDestAddrGroupRef).

- **IpService**
  If multiple IpService statements are specified in a rule, the rule is considered complex. Multiple IpService statements can be specified either inline or by referencing a group of IpService statements (IpServiceGroupRef).

- **IpService Direction**
  If the Direction parameter in an IpService statement is configured as bidirectional, the rule is considered complex.

Complex key exchange rules are split to produce multiple simple rules. The IKE daemon retrieves simple rules when necessary. The following conditions can make a complex key exchange rule:

- **LocalSecurityEndpoint Location**
  If multiple IP addresses (or address ranges) are specified in a local security endpoint, the associated key exchange rule is considered complex. You can specify multiple IP addresses by referencing a set or group of addresses from the local security endpoint (LocationGroupRef).

- **RemoteSecurityEndpoint Location**
  If multiple IP addresses (or address ranges) are specified in a remote security endpoint, the associated key exchange rule is considered complex. You can specify multiple IP addresses by referencing a set or group of addresses from the remote security endpoint (LocationGroupRef).

For more details on these IPSec policy configuration statements and parameters, see z/OS Communications Server: IP Configuration Reference.

The `pasearch` command displays IP filter rules and key exchange rules as complex rules, and not split as installed in the TCP/IP stack or retrieved by the IKE daemon.

For IP filter rules and key exchange rules, the condition level summaries are not applicable and are always displayed as all zeros.

**AT-TLS policy**

Policy conditions consist of a variety of selection criteria that act as filters for AT-TLS rules. Traffic can be filtered based on local addresses, remote addresses, local port range, remote port range, job name, user identification, and direction. For more details, see Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1093.
AT-TLS policy rules can refer to one or more policy conditions. A policy rule with a single policy condition is known as a simple rule, while one with more conditions is known as a complex rule. Complex AT-TLS policy rules have their conditions evaluated according to Conjunctive Normal Form (CNF), which means an ANDed set of ORed conditions. For details on CNF, see “Policy object model overview” on page 1347.

When AT-TLS rules are read and parsed, Policy Agent creates the rule as a complex rule. For example, consider the following TTLSRule statement:

```
TTLSRule ttlsRule1
{
    LocalAddrGroupRef    addrGroup1
    RemoteAddrGroupRef   addrGroup2
    LocalPortGroupRef    portGroup1
    RemotePortGroupRef   portGroup2
    Jobname              jobABC
    Userid               user1
    Direction            Outbound
    TTLSGroupActionRef   ttlsAction7
}
IpAddrGroup addrGroup1
{
    IpAddr
    { 
        Addr 9.1.1.1
    }
    IpAddr
    { 
        Addr 10.1.1.1
    }
}
IpAddrGroup addrGroup2
{
    IpAddr
    { 
        Addr 200.1.1.1
    }
    IpAddr
    { 
        Addr 201.1.1.1
    }
}
PortGroup portGroup1
{
    PortRange
    { 
        Port 21
    }
    PortRange
    { 
        Port 23
    }
}
PortGroup2
{
    PortRange
    { 
        Port 10
    }
    PortRange
    { 
        Port 15
    }
}
```

This rule is represented as a CNF rule with the following condition levels (levels are ANDed together):

- Level 1 = local address 9.1.1.1 OR local address 10.1.1.1
- Level 2 = remote address 200.1.1.1 OR remote address 201.1.1.1
- Level 3 = local port 21 OR local port 23
- Level 4 = remote port 10 OR remote port 15
The `pasearch` command displays the AT-TLS policy as complex rules.

**Policy-based routing policy**

Policy conditions consist of a variety of selection criteria that act as filters for policy-based routing (Routing) rules. Traffic can be filtered based on source addresses, destination addresses, source port range, destination port range, protocol, job name, security zone, and security label. For more details, see “Policy-based routing” on page 335.

Routing policy rules can refer to one or more policy conditions. A policy rule with a single policy condition is known as a simple rule, and one with more conditions is known as a complex rule. Complex routing policy rules have their conditions evaluated according to Conjunctive Normal Form (CNF), which means an ANDed set of ORed conditions. For details about CNF, see “Policy object model overview” on page 1347.

When routing rules are read and parsed, Policy Agent creates the rule as a complex rule. For example, consider the following RoutingRule statement:

```
RoutingRule rule1
{
  TrafficDescriptorGroupRef tdGroup
  IpSourceAddrGroupRef       addrGroup
  RoutingActionRef           action1
}
TrafficDescriptor td1
{
  SourcePortRange 1-5
  DestinationPortRange 10
  SecurityZone      zone1
  SecurityLabel     label1
  JobName           jobABC1
}
TrafficDescriptor td2
{
  SourcePortRange 6-9
  DestinationPortRange 25
  SecurityZone      zone2
  SecurityLabel     label2
  JobName           jobABC2
}
TrafficDescriptorGroup tdGroup
{
  TrafficDescriptorRef td1
  TrafficDescriptorRef td2
}
IpAddrGroup addrGroup
{
  IpAddr
  
  Addr 9.1.1.1
  
  IpAddr
  
  Addr 10.1.1.1
}
```

This rule is represented as a CNF rule with the following condition levels (levels are ANDed together):

- Level 1 = source address 9.1.1.1 OR source address 10.1.1.1
- Level 2 = (source port range 1-5 AND destination port range 10 AND job name jobABC1 AND security zone zone1 AND security label label1) OR (source port range 6-9 AND destination port range 25 AND job name jobABC2 AND security zone zone2 AND security label label2)

The `pasearch` command displays the Routing policy as a complex rule.
Policy configuration files

A single file, the main configuration file, is specified explicitly or by default when the Policy Agent is started. This main configuration file points to other configuration files, as shown in Figure 103 on page 779.

Figure 103. Policy Agent configuration files

For more information about the Policy Agent search order, see z/OS Communications Server: IP Configuration Reference.

You can specify statements in all configuration files using a variety of EBCDIC code pages. Use the Codepage configuration statement in the main configuration file to specify the code page to be used for all configuration files. The default code page is IBM-1047.

The main configuration file contains TcpImage or PEPInstance statements that define the TCP/IP stacks to be configured. The Policy Agent reads and installs policies for this set of stacks. Each TcpImage or PEPInstance statement can optionally specify the file name of an image-specific configuration file for that stack. If this file name is not specified, the main configuration file is also the image-specific configuration file for that stack. Thus, a single physical file can serve as two distinct logical files.

The main configuration file can also contain statements that specify the file names of one or more common configuration files for certain policy types. For example, the CommonIDSConfig statement points to a file containing IDS configuration statements that can be used for all configured stacks.

Each image-specific configuration file can contain statements that specify the file names of image-specific configuration files for different policy types. For example, the IPSecConfig statement points to a
Steps for configuring the Policy Agent

Details for each general step are described in a corresponding subtopic.

**Before you begin**
You need to understand the hierarchy and relationships of the different configuration files. For more information, see “Policy configuration files” on page 779.

**Procedure**
Perform the following steps to configure the Policy Agent:
1. Configure general information.
2. Configure Policy Agent as a policy server.
3. Configure Policy Agent as a policy client.
4. Configure policies in Policy Agent configuration files.
5. Configure Policy Agent to use the LDAP server using the ReadFromDirectory statement.
6. Configure Policy Agent for configuration file import services.

**Step 1: Configure general information**
Before defining policies, you need to configure some basic operational characteristics of the Policy Agent.

**Procedure**
Follow these steps to configure these characteristics:
1. Set the TZ and LIBPATH environment variables.
   Use the TZ environment variable to specify the correct time zone. Use the LIBPATH environment variable so that the required dynamic link library (DLL) files can be located when you start the Policy Agent. For information about how to specify these environment variables, see “Starting and stopping the Policy Agent” on page 795. You can also refer to comments in the sample start procedure that is shipped in SEZAINST(EZAPAGSP).
2. Specify the name of the main configuration file.
   You can specify the name of the main configuration file using the following methods:
   - `-c` start option
   - `PAGENT_CONFIG_FILE` environment variable
   - Default file name /etc/pagent.conf
   For information about the search order that Policy Agent uses to locate the main configuration file, and for examples of different ways to specify the main configuration file name, see “Starting and stopping the Policy Agent” on page 795. You can also refer to comments in the sample start procedure that is shipped in SEZAINST(EZAPAGSP).
3. Define the TcpImage or PEPInstance statements in the main Policy Agent configuration file.
The PEPInstance statement is a synonym for TcpImage, and either can be used. PEPInstance refers to policy enforcement point (PEP), the component of a policy system that enforces policies, which for z/OS is the TCP/IP stack.

**Results:**

- The refresh interval used for the main configuration file will be the smallest of the values specified for the image-specific configuration files.
- When the main configuration file is an MVS data set, it is reread at each refresh interval (which is the smallest of the individual stack refresh intervals), regardless of whether it has actually been changed or not. Because Policy Agent restarts all stack-related processing when the main configuration file is reread, this effectively makes the refresh interval for all stacks the same as this smallest configured interval.
- The TcpImage or PEPInstance statement and all its parameters have no effect on policies defined for policy clients.

To install a common set of policies to a set of stacks served by a single Policy Agent, do not specify image-specific configuration files for each image. In this case, there is only one configuration file (the main one) and the policy information contained in it is installed to all of the configured stacks. Different refresh intervals can also be configured for each image, but would probably be less useful in this case.

In either case, it is possible that TCP/IP stacks configured to the Policy Agent are not started or even defined. The Policy Agent will fail when trying to connect to those stacks and log appropriate error messages.

**Rule:** To dynamically add a TCP/IP stack to the Policy Agent configuration and have active policies automatically installed, in addition to adding the TcpImage statement to the configuration file, further action might be necessary as follows:

- If the Policy Agent was started with the -i startup option, no further action is necessary. Active policies will be automatically installed to the stack when it becomes active.
- If the Policy Agent was not started with the -i startup option, take one of the following actions:
  - Issue the MODIFY REFRESH or MODIFY UPDATE command after the stack becomes active. If you issue the MODIFY REFRESH or MODIFY UPDATE command before the stack becomes active, policies are not automatically installed.
  - Wait on the next update interval to check for configuration changes. If the stack is not active, policies are not automatically installed.

The Policy Agent does not end when any (or all) stacks end. When the stacks are restarted, active policies are automatically reinstalled.

The TcpImage statement specifies a TCP/IP image and its associated configuration file to be installed to that image. The following example installs the policy control file /tmp/TCPCS.policy to the TCPCS TCP/IP image, after flushing the existing policy control data:

```
TcpImage TCPCS /tmp/TCPCS.policy FLUSH
```

For information about the FLUSH, NOFLUSH, PURGE, and NOPURGE parameters, see “FLUSH and PURGE considerations” on page 799.

4. Define the log file destination and the appropriate logging level.

You can specify that Policy Agent log messages should be written to the syslog daemon or to a z/OS UNIX file. To indicate the syslog daemon, specify SYSLOGD in uppercase. To indicate a z/OS UNIX file, specify the file name. Specify the log file destination using the -l start option or the PAGENT_LOG_FILE environment variable, or you can use the default value /tmp/pagent.log.

**Tip:** Specify SYSLOGD to take advantage of a centralized logging mechanism.

**Result:** If Policy Agent cannot read the start options, then it does not have a log file destination. Policy Agent might fail to open a z/OS UNIX log file. In these situations, Policy Agent logs error messages to the syslog daemon and exits abnormally.
Guidelines: If you run Policy Agent with a nonzero UID and you are using a z/OS UNIX log file, follow these guidelines:

- Specify the file permissions as either 776 or 766.
- Make sure that the syslog daemon is not configured to log to the same z/OS UNIX file. The syslog daemon runs with UID 0, so Policy Agent might not be able to access its log file if the syslog daemon creates the file before Policy Agent starts.

The LogLevel statement is used to define the amount of information to be logged by the Policy Agent. The default is to log only event, error, console, and warning messages. This might be appropriate for a stable policy configuration, but more information might be required to understand policy processing or debug problems when first setting up policies or when making significant changes. Specify the LogLevel statement with the appropriate logging level in the main configuration file.

Note: The maximum logging level (511) can produce a significant amount of output, especially with large LDAP configurations. This is not a concern if a z/OS UNIX log file is used, because Policy Agent uses a set of log files with a finite size in a round-robin configuration (the number and size of these files is controllable with the PAGENT_LOG_FILE_CONTROL environment variable). But when using the syslog daemon as the log file, the amount of log output produced should be taken into consideration.

5. Provide the following security authorizations.
Because the Policy Agent can affect system operation significantly, the following security authorizations are required.

- A user starting Policy Agent must be a superuser.
- Security product authority (for example, RACF(R)) is required to start the Policy Agent. For sample commands needed to create the profile name and permit users to it, see the EZARACF sample in SEZAINST.

6. If Policy Agent's PAPI clients, including the pasearch command, are not defined as a superuser, to retrieve policies you must define security product authority in the SERVAUTH class for that client.
The security product authority is always required in cases where the image name cannot be defined as a superuser. Remote policy clients are never defined as a superuser on the policy server, so security product authority is always required for them. These profiles can be defined by image name and policy type (ptype = QoS, IDS, IPSec, TTLS, or Routing). Using a wildcard for profile names is allowed.

```
EZB.PAGENT.sysname.image.ptype
```

where:

- sysname - System name defined in sysplex
- image - Tcp name, policy client name, or import request name for policy information that is being requested
- ptype - Type that is being requested:
  - QOS - Policy QoS
  - IDS - Policy IDS
  - IPSec - Policy IPSec
  - TTLS - Policy AT-TLS
  - Routing - Policy Routing
  - CFGSERV - TCP/IP profile information
For details about the import request name, see “Configuration file import services” on page 770.

Tip: You can specify a wildcard on segments of the profile name.

Rules:
When you use policy clients, the image portion of the profile name on the policy server must match or include the name of the policy clients. Configure each policy client name using the ClientName parameter on the PolicyServer statement, or use the default value for the ClientName parameter. For information about specifying the client name on the PolicyServer statement, see z/OS Communications Server: IP Configuration Reference.

When you use import requesters, the image portion of the profile name on the policy server must match or include the import request name. If you use the IBM Configuration Assistant for z/OS Communications Server as the import requester, configure the import request name on the Import Policy Data panel or on request panels for discovery import. For information about the import request name, see “Configuration file import services” on page 770.

Policy Agent checks all client requests to verify that the SERVAUTH class is active and that the profiles exist for the images and types in the request.

If a client’s request is for multiple images or policy types, and permission is granted for only a subset of what is requested, Policy Agent returns only information for the subset for which permission is granted. However, if permission is denied for an entire request, including instances when only a single image or policy type is requested, an error is returned to the client indicating that permission is denied.

If the SERVAUTH class is not active or profiles are not active for the client’s request (image, policy type), an error is returned to the client indicating that permission is denied.

See the EZARACF sample in SEZAINST for sample commands needed to create the profile name and permit users to it.

**Step 2: Configure Policy Agent as a policy server**

Define the port for clients to connect, and policy client matching statements to select the configuration files to be used for clients. Create user IDs on the server to match the user IDs of clients, and set up security.

**Procedure**

If you want to use the Policy Agent as a policy server, perform these steps:

1. Define the port to which policy clients will connect.
   - If policy clients are to be used, the ClientConnection statement in the main configuration file provides the port that Policy Agent listens on for remote connections. You can use the default port (16310), but you must specify the ClientConnection statement to use Policy Agent as a policy server.
     
     **Guideline:** Reserve the port specified on the ClientConnection statement using the PORT statement in the TCP/IP profile.

     **Restriction:** The port value cannot match the port value that is configured on the ServicesConnection statement.

2. Define a set of policy client matching statements that select the configuration files to be used for policy clients.
   - When a policy client connects to the policy server, the DynamicConfigPolicyLoad statements in the main configuration file are evaluated to determine whether there is a match. The names are case sensitive with regard to matching. When a matching statement is found, the parameters identify both common and image-specific configuration files to be used for the policy client. If no matching statement is found, a default image-specific file is used. A matching statement (or default values) is bound to a policy client for the life of that client, until one of the following events occur:
     - The policy client disconnects from the policy server.
     - The connection between the policy server and policy client ends.
     - The associated DynamicConfigPolicyLoad statement is removed. In this case, the policy client is bound to a different DynamicConfigPolicyLoad statement (or to default values).

   You can use a regular expression for the policy client name on the DynamicConfigPolicyLoad statement to cause the statement to match multiple policy clients. For a description of supported regular
expressions on the DynamicConfigPolicyLoad statement, see z/OS Communications Server: IP
Configuration Reference.

For example, the expression (.+)_(.+), see z/OS Communications Server: IP
Configuration Reference.

For example, the expression (.+)_(.+), matches any client name composed of one or more characters,
followed by an underscore, followed by one or more characters. The default client names configured
on the PolicyServer statement on the policy client would match this expression.

You can use two different methods to substitute all or part of the client name in parts of the image-
specific file name.

- A single wildcard character (*) is replaced with the entire client name.
- If you use a regular expression as the DynamicConfigPolicyLoad statement client name, you can use
  the symbolic replacement values $0 through $9 in the image-specific file name. The value $0
  represents the entire portion of the client name that matched, while the values $1 through $9
  represent portions of the client name that match corresponding parenthesized sub-expressions in
  the regular expression. Using the regular expression (.+)_(.+), as an example, and a policy client
  name of SYS123_TCPIP2, the values of the possible replacement variables are as follows:
    - The value * is replaced with SYS123_TCPIP2
    - The value $0 is replaced with SYS123
    - The value $1 is replaced with TCPIP2
    - The value $2 is replaced with TCPIP2

In this example, the value $0 is the same as the value * but this does not hold true for all regular
expressions. If you want to use the entire client name as a replacement value, specify the value *.

The matching hierarchy used is as follows:

a. Exact match between the policy client name and the DynamicConfigPolicyLoad statement.
b. Regular expression match between the policy client name and the DynamicConfigPolicyLoad
   statement. The longest matching regular expression is chosen. If multiple statements match with
   the same length clientname parameter, the statement chosen is based on alphabetical order.
c. No matching statement. A default file is used based on the policy type, as follows:

<table>
<thead>
<tr>
<th>Policy type</th>
<th>Default file</th>
</tr>
</thead>
<tbody>
<tr>
<td>AT-TLS</td>
<td>/etc/pagent_remote.ttls</td>
</tr>
<tr>
<td>IDS</td>
<td>/etc/pagent_remote.ids</td>
</tr>
<tr>
<td>IPSec</td>
<td>/etc/pagent_remote.ipsec</td>
</tr>
<tr>
<td>QoS</td>
<td>/etc/pagent_remote.qos</td>
</tr>
<tr>
<td>Routing</td>
<td>/etc/pagent_remote.routing</td>
</tr>
</tbody>
</table>

The following example shows the DynamicConfigPolicyLoad statement matching by using a regular
expression to simulate a simple wildcard, and the resulting configuration files that are used, using
IPSec policies.

```plaintext
DynamicConfigPolicyLoad  Rem.*
{  PolicyType             IPSec
   {     CommonPolicyLoad   //ETC.COMMON.IPSEC
         PolicyLoad       //ETC.IPSEC(*)
   }
}
DynamicConfigPolicyLoad  Remote.*
{  ...
```
The resulting configuration files used for a variety of policy clients are shown in Table 40 on page 785:

<table>
<thead>
<tr>
<th>Policy client name</th>
<th>Matching statement</th>
<th>Common IPSec configuration file</th>
<th>Image IPSec configuration file</th>
</tr>
</thead>
<tbody>
<tr>
<td>Remote1</td>
<td>Remote.*</td>
<td>None</td>
<td>/etc/Remote1.ipsec</td>
</tr>
<tr>
<td>Remote5</td>
<td>Remote5</td>
<td>/user10/common_remote.ipsec</td>
<td>/user10/pagent_remote5.ipsec</td>
</tr>
<tr>
<td>Rem42</td>
<td>Rem.*</td>
<td><code>'ETC.COMMON.IPSEC'</code></td>
<td><code>'ETC.IPSEC(REM42)'</code></td>
</tr>
<tr>
<td>remote5</td>
<td>Not applicable</td>
<td>None</td>
<td>/etc/pagent_remote.ipsec</td>
</tr>
</tbody>
</table>

The following example shows the DynamicConfigPolicyLoad statement matching by using a more complex regular expression, and the resulting configuration files that are used, using IDS policies. The regular expression matches two strings separated by an underscore character. Each string must begin with an uppercase alphabetic character and end with a numeric character.

```
{                          
  PolicyType             IDS
  {                      
    CommonPolicyLoad     `'ETC.COMMON.IDS'`
    PolicyLoad           `'ETC.$1($2)'`
  }
}
```

The resulting configuration files used for a variety of policy clients are shown in Table 41 on page 785:

<table>
<thead>
<tr>
<th>Policy client name</th>
<th>Matching statement</th>
<th>Common IDS configuration file</th>
<th>Image IDS configuration file</th>
</tr>
</thead>
<tbody>
<tr>
<td>SYS123_TCPPIP</td>
<td>Not applicable</td>
<td>None</td>
<td>/etc/pagent_remote.ids</td>
</tr>
</tbody>
</table>

**Rule:** The policy client names and DynamicConfigPolicyLoad statement names are case sensitive, but MVS data set names are not. Therefore, be careful when defining MVS data set configuration files that include a wildcard that is to be substituted with the policy client name. For example, the policy client
names client42 and Client42, if used as a substitution variable in an MVS data set name, would result in the same configuration file being used for both policy clients.

3. Configure one or more user IDs on the policy server system to match the user IDs of the policy clients. Each policy client uses a unique client name, but also must present valid credentials to the policy server. Valid credentials include a user ID and password or a user ID and PassTicket (if secure signon is enabled).

**Rule:** The password defined for the user ID must match the password configured using the AuthBy Password parameter on the PolicyServer statement on the policy client.

A SAF user ID representing a policy client must be defined to the security product. The user ID must be defined with an OMVS segment. When RACF is used as the security product, define the SAF user ID with the following command:

```
ADDUSER client PASSWORD(password) DFLTGRP(OMVSGRP) OMVS(UID(x) HOME('/home/client'))
```

Each policy client does not need to use a unique user ID, although that is a configuration option. The user ID is used for two purposes on the policy server:

- User authentication when the policy client connects to the policy server
- Access to SERVAUTH profiles to determine which policies the client can access

4. Permit Policy Agent to the BPX.DAEMON FACILITY class profile.

For information about the use of the BPX.DAEMON profile, see “BPX.DAEMON FACILITY class profile” on page 37. If you decide to use this profile, permit the Policy Agent user ID to it. When RACF is used as the security product, permit the user ID with the following command:

```
PERMIT BPX.DAEMON CLASS(FACILITY) ID(userid) ACCESS(READ)
```

5. If you want to use PassTicket security for policy clients, configure PTKTDATA class profiles.

Policy clients can be configured to use either a password or a PassTicket on the PolicyServer statement, used when they connect to the policy server. For information about the secured signon function and PassTickets, see z/OS Security Server RACF Security Administrator's Guide. If you choose to use PassTickets, define the appropriate profiles in the PTKTDATA class to contain the application key used to generate and validate the PassTicket. When RACF is used as the security product, define the profiles with the following command:

```
RDEFINE PTKTDATA profile SSIGNON(KEYMASKED(key)) UACC(UPDATE)
```

The application name used by Policy Agent is PAGENT, so you need to define a profile with this name. The application key defined in the profiles must be the same on the policy client and policy server.

6. If you want to use secure connections between policy clients and the policy server, configure AT-TLS rules on the policy server to enable SSL connections from the policy clients.

If policy clients use SSL connections, you must define AT-TLS rules on the policy server for communications between the policy client and server to be secured using AT-TLS. AT-TLS processing for a stack is enabled by specifying the TTLS parameter on the TCPCONFIG statement in the TCP/IP profile. Specific AT-TLS policy is configured in Policy Agent configuration files. For details about enabling AT-TLS and configuring AT-TLS policy, see Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1093.

**Rules:**

- Define AT-TLS policy such that only cipher suites requiring TLS encryption are exchanged with policy clients. Failure to restrict the cipher suites to those requiring encryption might result in sensitive information flowing in the clear across an untrusted network.
- Define AT-TLS policy for each stack through which policy server and policy client communication can flow.
- If some policy clients use SSL and others do not use SSL, define AT-TLS policy to select only those policy clients that use SSL.
Result: If you choose not to use SSL for your policy client to policy server connections, sensitive information flows in the clear on the connections. Sensitive information includes, but is not limited to, the following information:

- The password that is sent from the policy client to the policy server for authentication (if you are using password credentials)
- Policy information that is sent from the policy server to the policy client, such as:
  - Passwords
  - Certificate labels
  - IPSec keys for IKE tunnels that use pre-shared keys
  - IPSec keys for manual tunnels

Requirement: The policy server acts as the server during an SSL handshake. To act in the server role of an SSL handshake, the policy server must have access to a private key and certificate verifying its ownership of that private key. For information about creating and managing keys and certificates for servers that use AT-TLS, see Appendix B, “TLS/SSL security,” on page 1299.

An example of the AT-TLS policy statements used to enable AT-TLS for the policy server is as follows:

```
TTLSRule PolicyServerRule
{
    LocalPortRange 16310
    JobName PAGENT
    Direction Inbound
    TTLSGroupActionRef PolicyServerGroup
    TTLSEnvironmentActionRef PolicyServerConn
}

TTLSGroupAction PolicyServerGroup
{
    TTLSEnabled On
}

TTLSEnvironmentAction PolicyServerConn
{
    TTLSKeyRingParms
    {
        Keyring PAGENT/keyring
    }
    TTLCipherParmsRef RequireEncryption
    HandshakeRole SERVER
}

TTLCipherParms RequireEncryption

    V3CipherSuites TLS_RSA_EXPORT_WITH_RC4_40_MD5
    V3CipherSuites TLS_RSA_WITH_RC4_128_SHA
    V3CipherSuites TLS_RSA_WITH_DES_CBC_SHA
    V3CipherSuites TLS_RSA_WITH_DES_CBC_SHA
    V3CipherSuites TLS_RSA_WITH_DES_CBC_SHA
    V3CipherSuites TLS_RSA_WITH_DES_CBC_SHA
    V3CipherSuites TLS_RSA_WITH_DES_CBC_SHA
    V3CipherSuites TLS_RSA_WITH_RC4_128_SHA
    V3CipherSuites TLS_RSA_WITH_RC4_128_SHA
    V3CipherSuites TLS_RSA_EXPORT_WITH_RC2_CBC_40_MD5
    V3CipherSuites TLS_RSA_EXPORT_WITH_RC4_40_MD5
}
```
**Rule:** The LocalPortRange value on the TTLSRule statement must include the value specified on the ClientConnection statement in the policy server main configuration file.

7. If you use secure connections between any policy clients and the policy server, permit Policy Agent to the EZB.INITSTACK.sysname.tcpname SERVAUTH class profile.

   Because AT-TLS policies are used to enable SSL connections from policy clients, Policy Agent must be permitted to the EZB.INITSTACK.sysname.tcpname SERVAUTH class profile if any policy clients use SSL. For more details, see “TCP/IP stack initialization access control” on page 1094. When RACF is used as the security product, permit Policy Agent to the profile with the following command:

   ```
   PERMIT EZB.INITSTACK.sysname.tcpname CLASS(SERVAUTH) ID(userid) ACCESS(READ)
   ```

**Step 3: Configure Policy Agent as a policy client**

You can use the Policy Agent as a policy client.

**Procedure**

If you want to use the Policy Agent as a policy client, perform the following steps:

1. Define the parameters needed to connect to the policy server using the ServerConnection statement in the main configuration file:
   - Specify the host name (or IP address) and port of a primary and an optional backup server.
   - If you want to use a secure connection to the policy server, specify parameters for a secure SSL connection. For details, see “Add SSL to Policy Agent connections” on page 793.

   **Requirement:** Connectivity to the policy server is required for all images on the policy client that need to connect to the policy server.

2. Define the policy server parameters to be used for each image on the PolicyServer statement in the image configuration files:
   - When the policy client connects to the policy server, the policy client needs to supply a user ID and authentication information (password or PassTicket). Specify these parameters on the PolicyServer statement. The user ID must be defined on the policy server system. For information about the PTKTDATA class profiles that are needed when a PassTicket is specified on the PolicyServer statement, see step “5” on page 786 in “Step 2: Configure Policy Agent as a policy server” on page 783.
   - The policy server determines what configuration files to load based on a matching DynamicConfigPolicyLoad statement in its configuration. Specify the client name that the policy server is to use for matching. If this parameter is not specified, the default value is the policy client's system name concatenated to the image name with an intervening underscore character (_). For example, if the client's system name is SYS42 and the image name for this policy client is TCPIP2, the default client name presented to the policy server is SYS42_TCPIP2.
   - Specify the types of policies to be retrieved from the policy server. You can specify one or more policy types. You can also specify parameters for each policy type (FLUSH, NOFLUSH, PURGE, or NOPURGE). These parameters have the same meaning as the corresponding parameters on the TcpImage or PEPInstance statement.

   For each policy type specified, the corresponding xxxConfig statement for that type is ignored in the local configuration. For example, if PolicyType IPSec is specified on the PolicyServer statement, the IPSecConfig statement is ignored. This is true even if the primary and backup policy servers cannot be reached. You can use local or remote policy for each policy type, but not both.

**Step 4: Configure policies in Policy Agent configuration files**

Policies can be defined in any referenced Policy Agent configuration file. For more information, see the appropriate information for each policy type:

- Policy-based routing (See “Policy-based routing” on page 335)
- Quality of Service (See Chapter 15, “Quality of service,” on page 803)
• Intrusion detection services (See Chapter 16, “Intrusion detection services,” on page 823)
• IP filtering, and manual and dynamic VPN tunnels, collectively referred to as IPSec policies (See Chapter 17, “IP security,” on page 855)
• Application Transparent Transport Layer Security (See Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1093)

Step 5: Configure Policy Agent to use the LDAP server using the ReadFromDirectory statement

The ReadFromDirectory statement in the Policy Agent configuration file initializes the Policy Agent as an LDAP client. The policies are downloaded from the LDAP server, along with the policies specified in the Policy Agent configuration files.

When configuring the ReadFromDirectory statement, first specify the name (or IPv4 address) and port of the primary server and the same for the backup server (if one is used).

Notes:

1. The LDAP client library used to connect to the LDAP server does not support IPv6.
2. When using the z/OS LDAP server, the server listens on a separate port for SSL connections. This means that you should specify the correct port depending on whether or not SSL is used.

Next, configure other connection attributes. The Policy Agent (as an LDAP client) must log in to the LDAP server. The user ID and password for logging in must be configured on the ReadFromDirectory statement. The user ID is also known as Distinguished Name for user ID, and it is in the form of an LDAP DN. If the user ID and password are not specified, the Policy Agent uses anonymous login to connect to the server.

The LDAP server can be configured with only LDAP protocol version 3. To use LDAP protocol version 3, you can set LDAP_ProtocolVersion to 3 on the ReadFromDirectory statement. This is the default value. This statement also configures the version of the schema to be retrieved from the server.

Finally, configure attributes to indicate how to search the LDAP server for policies. Policy roles allow one or more roles, or role-combinations, to be assigned to policy rules using the ibm-policyRoles attribute. These roles represent the intended usage of the policy rules. For example, a role of “East Coast WAN” might be used to represent policies for the wide area network on the US East coast for an enterprise. Policy role values are not standardized; they are simply values used to assign roles to policies. When an entity that requires policies (such as Policy Agent) requests policies from an LDAP server, it can filter out policy rules that do not match the roles that it plays. Although similar to policy keywords, which also allow search scoping, policy roles are a bit more sophisticated. Specifically, role-combinations are allowed, which take the form of a specification like “roleA && roleB”, meaning both roleA AND roleB. Because the ibm-policyRoles attribute is multi-valued, a form of CNF/DNF logic can be used for policy roles: the roles in a role-combination are ANDed, and the roles or role-combinations specified on different values of this attribute are ORed.

For the Version 1 schema, a base DN to start the search, and a selector tag value are configured. The selector tag is used to match against the SelectorTag attribute in the policy objects. For Version 1, the Policy Agent also automatically includes the stack name when searching for policies; this value is matched against the TcpImageName attribute in the policy objects. For the Version 2 schema, a base DN to start searching is also configured. This DN can specify a single LDAP object, a policy group, or an LDAP subtree containing many objects. For filtering the search, three keywords can be configured:

• SearchPolicyKeyword matches against the ibm-policyKeywords attribute in any policy object.
• SearchPolicyGroupKeyword matches against the ibm-policyGroupKeywords attribute in policy group objects.
• SearchPolicyRuleKeyword matches against the ibm-policyRuleKeywords attribute in policy rule objects.

Optionally, specify parameters for a secure SSL connection. For details, see “Add SSL to Policy Agent connections” on page 793.

The example that follows this list takes the following actions:
Step 6: Configure Policy Agent for configuration file import services

You can connect an import requester to the Policy Agent to provide policy configuration file or TCP/IP profile information import services.

Procedure

To configure the Policy Agent for configuration file import services, perform the following steps:

1. Define the port and TCP/IP image name to which import requesters will connect.

   If import requesters are to be used, the ServicesConnection statement in the main configuration file provides the port and TCP/IP image name that the Policy Agent listens on for remote connections. An import requester is one type of services requester provided for by the ServicesConnection statement. The Policy Agent listens for services requester connections on only one TCP/IP image. You can specify the image name to be used, or use the name specified (or specified by default) on the TCPIPUSERID statement or TCPIPJOBNAME statement in TCPIP.DATA. If the default TCP/IP image cannot be determined, the Policy Agent uses the image name INET. In any case, the image name might or might not match an image name specified on a TcpImage statement:

   - If the specified name does not match any TcpImage statement, the Policy Agent generates an internal TcpImage statement with default values to represent the TCP/IP image. This means that you can specify a maximum of only 7 (instead of 8) TcpImage or PEPInstance statements.
   - In a single stack (INET) environment, the Policy Agent uses the active TCP/IP image to listen for services connection requests.

   Rule: The ServicesConnection statement is required for any Policy Agent that accepts connections from an import requester.

   Guideline: Reserve the port specified on the ServicesConnection statement using the PORT statement in the TCP/IP profile.

   Restriction: The port value cannot match the port value configured on the ClientConnection statement.

2. Optionally configure secure connections from the import requesters.

   - By default, the ServicesConnection statement defines a basic connection that is not explicitly secured. This option can be used for an unsecure connection, or you can define AT-TLS policies for this import services connection to create a secure SSL connection.

   - You can define a secure connection instead, and specify the level of tracing and the TLS/SSL key ring to use. You must specify the name of a SAF key ring. Key ring files created by the System SSL gskkyman utility are not supported. When you configure a secure connection, Policy Agent automatically creates an AT-TLS policy for the connection, and the import requester must also...
specify that the connection is to be secured. You must enable the TTLS parameter on the
TCPCONFIG statement in the TCP/IP profile for the generated AT-TLS policy to be effective.

**Tip:** This option only supports TLSv1.0 and is not recommended for secure SSL. It is recommended for
secure SSL to configure Security Basic and to supply user defined AT-TLS policies.

The following example shows a ServicesConnection statement for a secure connection:

```
ServicesConnection
{
  Port       17000
  ImageName  TCPIP1
  Security   Secure
  Trace      14
  Keyring    PAGRING
}
```

The following AT-TLS policy is generated from this ServicesConnection statement:

```
TTLSRule                      TTLS_RULE_______________GENERATED
{
  LocalPortRange             17000
  JobName                    PAGENT
  Direction                  Inbound
  TTLSGroupActionRef         TTLS_GROUP_ACTION_______GENERATED
  TTLSEnvironmentActionRef   TTLS_ENVIRONMENT_ACTION_GENERATED
}
TTLSGroupAction               TTLS_GROUP_ACTION_______GENERATED
{
  TTLSEnabled                On
  Trace                      14
}
TTLSEnvironmentAction         TTLS_ENVIRONMENT_ACTION_GENERATED
{
  HandshakeRole              SERVER
  TTLSKeyRingParms
  {
    Keyring                 PAGRING
  }
}
```

The Policy Agent installs this generated policy in the TCP/IP image specified explicitly or by default on
the ServicesConnection statement. This generated policy uses a priority value that is lower than any
specified AT-TLS policies, so it is installed as the last policy in the TCP/IP image. If local or remote AT-
TLS policies are configured, the Policy Agent installs those policies before installing the generated
policy. If you configure AT-TLS policies on a policy server, those policies must be successfully retrieved
before the Policy Agent is able to accept connections from services requesters. Accepting connections
from services requesters can be affected by problems or delays in retrieving the AT-TLS policies from
the policy server.

If you change the ServicesConnection statement, the generated policy is uninstalled or reinstalled as
follows:

- If you change the Port, Trace or Keyring parameters, the Policy Agent regenerates and reinstalls the
  policy.
- If you change the ImageName parameter, the Policy Agent uninstalls the generated policy from the
  previous image and installs the policy on the new image.
- If you change the Security parameter value from Secure to Basic, the Policy Agent uninstalls the
  generated policy.
- If you delete the ServicesConnection statement, the Policy Agent uninstalls the generated policy.

3. To restart the listen for services requester connections and, if required, to reinstall the generated AT-
TLS policy, issue the MODIFY SRVLSTN command. For information about when you might use the
MODIFY command for Policy Agent, see z/OS Communications Server: IP System Administrator's
Commands.
Step 7: Configuring Policy Agent to automatically monitor applications

You can use the Policy Agent to automatically start, stop, and monitor a set of related applications. Policy Agent starts the applications and monitors them to ensure that they remain active.

Before you begin

If Policy Agent determines that any applications have not started or have stopped, it continues to try to start or restart the applications, up to a configurable retry limit within a configurable retry period.

Requirement: To automatically monitor applications, you must start Policy Agent with a user ID that has superuser authority UID(0). For sample RACF commands, see the EZARACF member of SEZAINST.

Procedure

To configure the Policy Agent for automatic monitoring, perform the following steps:

1. Decide what applications you want to monitor.
   
   You can use the Policy Agent to monitor any or all of the following applications:
   
   • Defense Manager daemon (DMD)
   • Internet Key Exchange daemon (IKED)
   • Network security services daemon (NSSD)
   • Syslog daemon (SYSLOGD)
   • Traffic Regulation Management daemon (TRMD)

   Determine which of these applications you currently use, or want to start using, in your environment, and for each application, determine whether you want the Policy Agent to start, stop, and monitor the application.

   Requirements:
   
   • To start the application, you must use a cataloged procedure that accepts a number of variables that are provided by the Policy Agent. A sample procedure is included in SEZAINST(EZAPOLPR).
   • If you want to manually start, restart, or stop the application, you must use MODIFY commands that are directed to the Policy Agent. If you issue the commands directly to the application itself, Policy Agent is not aware of the action and the monitoring logic will probably not produce the expected results.

   Results:
   
   • If you start the Policy Agent after you have already started an application to be monitored, Policy Agent starts monitoring the application if it was originally started with the same job name that is configured to the Policy Agent. If the application needs to be restarted later, it is restarted using the cataloged procedure configured to the Policy Agent. This might not be the same procedure that was originally used to start the application.
   • If you start the Policy Agent after you have already started an application to be monitored, but the application does not use the same job name that is configured to the Policy Agent, then the Policy Agent is not able to detect that the application is active. The Policy Agent will try to start another instance of the application, which is likely to fail.

   Tip: If you configure applications to be monitored by the Policy Agent, ensure those applications are not running before starting the Policy Agent. However, you probably want to start syslogd before starting the Policy Agent, so you should ensure that Policy Agent is configured with the correct syslogd job name.

2. Configure the applications that you want to monitor using the AutoMonitorApps statement.
   
   You can configure applications that you want to monitor that are or are not associated with a particular TCP/IP stack. You can specify the cataloged procedure used to start each application, the job name for the application, and other application-specific parameters on the AutoMonitorApps statement.

   Perform the following steps to configure the applications that you want to monitor:
a. Specify the AutoMonitorApps statement in the main Policy Agent configuration file.
   - Use the AppName parameter to specify each application that is not associated with a particular TCP/IP stack. All supported applications except TRMD fall into this category.
   - Use the TcpImageName and AppName parameters to specify each application that is associated with a particular TCP/IP stack. TRMD is the only application that falls into this category.

b. Use the ProcName parameter for each AppName parameter on the AutoMonitorApps statement to specify the cataloged procedure that is used to start each application. Because all key data is passed to the procedure as variables, you can use a single procedure for all configured applications. You can also use a unique procedure for one or more applications.

c. Use the Jobname parameter for each AppName parameter on the AutoMonitorApps statement to specify the job name for each application.

d. Use the StartParms parameter for each AppName parameter on the AutoMonitorApps statement to specify start parameters for each application.

e. Use one or more EnvVar parameters for each AppName parameter on the AutoMonitorApps statement to specify application-specific parameters, such as time zone or configuration file name. You can specify any or all environment variables that are accepted by the specific application.

The following example shows the AutoMonitorApps statement:

```
AutoMonitorApps
{
    AppName             IKED
        Procname        POLPROC
    }                  AppName             TRMD
        TcpImageName    TCPIP1
            Procname      POLPROC
            Jobname       TRMD1
    }                  TcpImageName    TCPIP3
            Procname      POLPROC
            Jobname       TRMD3
}
```

This example shows how to specify parameters for two types of applications:

   - An application without stack affinity, meaning that a single copy of the application runs regardless of how many TCP/IP stacks are running. This example uses IKED as such an application.
   - An application with stack affinity, meaning that one instance of the application runs on each TCP/IP stack. This example uses TRMD as such an application.

   Use the AutoMonitorParms statement in the main Policy Agent configuration file to specify global monitoring parameters, such as the monitor time interval and retry limits.

   - Use the MonitorInterval parameter to specify the monitor interval in seconds.
   - Use the RetryLimitCount and RetryLimitPeriod parameters to specify how many times within a given time period Policy Agent should try to start or restart an application. If the application fails to successfully start or restart after the retry limit has been reached, Policy Agent stops trying until the application is manually started using the MODIFY procname,MON,START,application command.

Add SSL to Policy Agent connections

The Secure Sockets Layer (SSL) protocol begins with a handshake. During the handshake, the client authenticates the server, the server optionally authenticates the client, and the client and server agree on how to encrypt and decrypt information.
Server Authentication: When using SSL to secure communications, the SSL authentication mechanism known as server authentication is used. With server authentication, the server must have a digital certificate that authenticates the server to the Policy Agent client. The server supplies the client with the certificate during the initial SSL handshake. If the client validates the server's certificate, a secure communication channel is established between the server and the Policy Agent client.

For server authentication to work, the server must have a private key and associated server certificate in the server key ring file.

To conduct commercial business on the Internet, you might use a widely known Certificate Authority (CA), such as VeriSign, to get a high assurance certificate. For a relatively small private network within your own enterprise or group, you can issue your own certificates, called self-signed certificates, for your own use.

Client Authentication: When using SSL Client Authentication, the client passes a digital certificate to the server as part of the SSL handshake. To pass authentication, the Certificate Authority (CA) that signed the client certificate must be considered trusted by the server.

Self-signed Server Certificates: Normally, a server certificate should be obtained from a known CA. However, for testing, an installation might use a self-signed server certificate. Because the clients will not know about the issuer of the self-signed server certificate, in most cases it is necessary to add the server's self-signed certificate to the client's signer certificates.

The gskkyman utility is used to create public/private key pairs and certificate requests, receive certificate requests into a key ring, and manage keys in a key ring. The gskkyman utility is documented in z/OS Cryptographic Services System SSL Programming. The gskkyman utility is shipped with z/OS in System SSL, which is part of the cryptographic services base element of z/OS. For detailed instructions on setting up certificates and key rings, see Appendix B, "TLS/SSL security," on page 1299.

The set of SSL protocol cipher specifications to be allowed for the secure session can be set for the policy server connection.

**Rule:** Define AT-TLS policy on the policy server such that only cipher suites requiring TLS encryption are exchanged with policy clients. Failure to restrict the cipher suites to those requiring encryption might result in sensitive information flowing in the clear across an untrusted network.

For the list of cipher suites supported and the default order used if none is specified, see z/OS Cryptographic Services System SSL Programming.

The Policy Agent connection to LDAP can be secured using SSL by tailoring the following parameters on the ReadFromDirectory statement. This allows for protection of policy retrieval from an LDAP server.

- LDAP_SSLKeyringFile
- LDAP_SSLKeyringPassword
- LDAP_SSLName

The policy client connection to the policy server can be secured using SSL by tailoring the following parameters on the ServerConnection statement. This allows for protection of policy retrieval from the policy server.

- ServerSSLEnterprise
- ServerSSLKeyringPassword
- ServerSSLKeyringStashFile
- ServerSSLName
- ServerSSLV3CipherSuites

You can secure the connection used by services requesters by tailoring the following parameters on the ServicesConnection statement. This provides protection of information retrieval by import requesters, such as the IBM Configuration Assistant for z/OS Communications Server.

- Security Secure
- Keyring
Starting and stopping the Policy Agent

You can start the Policy Agent in any of the following ways:

• From the z/OS shell
  If you use the shell, start the Policy Agent in a background shell session by specifying a trailing & on the command line.
• As a started task
• Using the COMMNDxx member of parmlib
  Using the COMMNDxx member of parmlib enables Policy Agent to be automatically started when the system is IPLed. For more information about COMMNDxx, see z/OS MVS Initialization and Tuning Reference.
• In some cases, using the TCP/IP AUTOLOG statement
  For more information, see “AUTOLOG considerations” on page 795.

AUTOLOG considerations

If a procedure in the AUTOLOG list also has a PORT statement reserving a TCP or UDP port but does not have a listening connection on that port, TCP/IP periodically attempts to cancel that procedure and start it again.

Guideline: Do not use AUTOLOG to start the Policy Agent if any listening connections are used. The Policy Agent is unlike typical servers, and performs functions outside the realm of listening for connections from other applications. Sometimes during normal operation of the Policy Agent, listening connections are unavailable for short periods of time. When listening connections are unavailable, it is possible that the AUTOLOG timer could restart the Policy Agent.

Policy Agent optionally listens on one or more of the following ports:

• The pagentQosListener port (usually defined in the /etc/services file as port 1700). This happens only when the PolicyPerfMonitorForSDR statement is configured for a given TCP/IP stack.
• The port defined or specified by default on the ClientConnection statement, which is used to listen for remote policy client connections on all TCP/IP stacks.
• The port defined or specified by default on the ServicesConnection statement, which is used to listen for services requester connections on a single TCP/IP stack. For information about the ServicesConnection statement and specifying which stack to use to listen for these connections, see z/OS Communications Server: IP Configuration Reference.

If you want to start Policy Agent with AUTOLOG, you must take one of the following actions:

• Ensure that none of the listening ports used by Policy Agent are reserved by the PORT statement in the TCP/IP profile.
• Add the NOAUTOLOG parameter to the PORT statement in the TCP/IP profile. For example:

<table>
<thead>
<tr>
<th>PORT</th>
<th>1700</th>
<th>TCP PAGENT NOAUTOLOG</th>
</tr>
</thead>
<tbody>
<tr>
<td>16310</td>
<td>TCP PAGENT NOAUTOLOG</td>
<td></td>
</tr>
<tr>
<td>16311</td>
<td>TCP PAGENT NOAUTOLOG</td>
<td></td>
</tr>
</tbody>
</table>

In addition, when the PolicyPerfMonitorForSDR statement is being used, if the pagentQosCollector port (usually defined in the /etc/services file as port 1701) is reserved in the PORT list it should always be
specified with the NOAUTOLOG parameter, because this port is never used as a listening port. For example:

```
PORT
1701 TCP PAGENT NOAUTOLOG
```

**Tip:** When Policy Agent is not listening on any ports, you can use the autostart feature of AUTOLOG as previously described. However, the monitoring and automatic restart features of AUTOLOG are unavailable because AUTOLOG must listen to a TCP or UDP connection.

If you fail to take one of the above actions, Policy Agent will be periodically canceled and restarted by TCP/IP.

**Specifying environment variables**

The Policy Agent requires access to one or more DLLs at run time. The LIBPATH environment variable needs to be set to include the /usr/lib directory, which normally includes all the required DLLs.

For policy time specifications to be properly acted upon, the TZ environment variable needs to be set to local time. You can set the LIBPATH and TZ environment variables as follows:

- When starting from the z/OS shell:

  Export the LIBPATH and TZ environment variables before starting the Policy Agent. This is best accomplished in /etc/profile or in .profile in the HOME directory. For example, if you are in the Eastern time zone in the United States:

  ```
  export LIBPATH=/usr/lib
  export TZ=EST5EDT
  ```

- When starting as a started task, use either of the following methods:

  - Specify LIBPATH and TZ using the ENVAR parameter on the PARM statement in the started procedure. For example:

    ```
    // PARM=('ENVAR("LIBPATH=/usr/lib","TZ=EST5EDT")/')
    ```

  - Export the LIBPATH and TZ environment variables in a file specified with the STDENV DD statement. For example:

    ```
    // PARM='ENVAR(_CEE_ENVFILE=DD:STDENV)'/
    //STDENV DD PATH='/etc/pagent.env',PATHOPTS=(ORDONLY)
    ```

    In the /etc/pagent.env file:

    ```
    LIBPATH=/usr/lib
    TZ=EST5EDT
    ```

    The use of the STDENV DD statement works well when you want to specify more than one environment variable; there is a JCL limit of 100 characters on the PARM parameter. Language Environment recommends a variable record format for the STDENV file.

    You can also set the TZ environment variable for all applications in the CEEPRMxx PARMLIB member. You should define the TZ environment variable for all three LE option sets (CEEDOPT, CEECOPT, and CELQDOPT). For example:

    ```
    CEECOPT(ALL31(ON), ENVAR('TZ=EST5EDT'))
    CEECOPT(ALL31(ON), ENVAR('TZ=EST5EDT'))
    CELQDOPT(ALL31(ON), ENVAR('TZ=EST5EDT'))
    ```

    For more information on specifying run-time options, see z/OS Language Environment Programming Guide. For details on setting the LIBPATH and TZ environment variables, see z/OS UNIX System Services Command Reference.
Main configuration file search order

Although the /etc/pagent.conf is the default configuration file, a specific search order is used when starting the Policy Agent. The following order is used:

1. File or data set specified with the -c startup option
2. File or data set specified with the PAGENT_CONFIG_FILE environment variable
3. /etc/pagent.conf

The syntax for a z/OS UNIX file is different than the syntax for an MVS data set. The following examples use the PAGENT_CONFIG_FILE environment variable:

- PAGENT_CONFIG_FILE=/dir/file
- PAGENT_CONFIG_FILE=/'mvs.dataset.name'

Other considerations when starting the Policy Agent

If you start the Policy Agent with a user ID that does not have superuser authority [UID(0)], then read and write permission is required for the following directories and files:

- Directories
  - /tmp/
  - /var/tmp/
- Files
  - Files created when you configure the PerformanceLogFile parameter on the PolicyPerformanceCollection statement
    For information about the PolicyPerformanceCollection statement, see z/OS Communications Server: IP Configuration Reference.
  - Policy Agent log files
    For information about using the -l parameter when starting Policy Agent from the z/OS shell to specify the destination for the log file, see z/OS Communications Server: IP Configuration Reference.
  - Policy Agent pid file
    The /tmp/pagent.pid is a temporary file that the Policy Agent creates. This file contains the process ID of the current invocation of the Policy Agent.

Restrictions:

- If /tmp/pagent.pid is a symbolic link, it must have an owning UID or GID that matches the EUID or EGID that is assigned to the Policy Agent.
- If /tmp/pagent.pid is a hard link or the target of a hard link, users that are outside the owner or group of the directory in which /tmp/pagent.pid is stored cannot have write access to the directory. Additionally, write access to /tmp/pagent.pid must be limited to the owning UID or group, for example, --w--w----permissions.

Requirement: To automatically monitor applications, you must start Policy Agent with a user ID that has superuser authority UID(0). For sample RACF commands, see the EZARACF member of SEZAINST.

At initialization, the Policy Agent creates a z/OS UNIX file called /tmp/tcpname.Pagent.tmp. This occurs for every TCP/IP stack defined on a TcpImage statement.

In this z/OS UNIX file, tcpname is the name of a TCP/IP stack from a TcpImage statement. During TCP/IP stack initialization, the TCP/IP stack will attempt to modify a file by this name to notify the Policy Agent that the stack has been reactivated. This causes the Policy Agent to automatically attempt to reinstall the existing policies to this stack.

When /tmp/tcpname.Pagent.tmp is in a read/write sysplex-aware z/OS file system (zFS), a symbolic link can be created to a file that is in a hierarchical file system or in a read-only zFS to enable the update
notification. In the following example, the `ln` command is used to create a symbolic link to a file in `/mydir`, where `/mydir` is in an HFS or a read-only zFS:

```bash
ln -s /mydir/TCPIP.Pagent.link /tmp/TCPIP.Pagent.tmp
```

**Restrictions:**

- **Policy Agent**
  - If `/tmp/tcpname.Pagent.tmp` is a symbolic link, it must have an owning UID or GID that matches the EUID or EGID that is assigned to the Policy Agent.
  - If `/tmp/tcpname.Pagent.tmp` is a hard link or the target of a hard link, users that are outside the owner or group of the directory in which `/tmp/tcpname.Pagent.tmp` is stored cannot have write access to the directory. Additionally, write access to `/tmp/tcpname.Pagent.tmp` must be limited to the owning UID or group, for example, `--w--w----` permissions.

- **TCP/IP stack**
  - If `/tmp/tcpname.Pagent.tmp` is a symbolic link, it must have an owning UID or GID that matches the EUID or EGID that is assigned to the TCP/IP stack.
  - If `/tmp/tcpname.Pagent.tmp` is a hard link or the target of a hard link, users that are outside the owner or group of the directory in which `/tmp/tcpname.Pagent.tmp` is stored cannot have write access to the directory.

To ensure that only one Policy Agent is started, the Policy Agent uses the following enqueue:

- Enqueue name is TCP_TCPI
- Resource name is TCPIP.PAGENT

When starting from the shell, note that the Policy Agent executable file is in the `/usr/lpp/tcpip/sbin` directory. There is also a link from the `/usr/sbin` directory. Make sure your PATH statement contains either the `/usr/sbin` or `/usr/lpp/tcpip/sbin` directory.

For example, the following command starts Policy Agent with these characteristics:

```bash
pagent -c /u/user10/pldap.conf -l SYSLOGD &
```

- Policy Agent uses the configuration file `/u/user10/pldap.conf`
- Policy Agent logs output to the syslog daemon (SYSLOGD). Note that "SYSLOGD" must be specified in uppercase to obtain this behavior.

Use the `S PAGENT` command on an MVS console or SDSF to start the Policy Agent as a started task. A sample procedure is shipped in member EZAPAGSP in SEZAINST.

**Stopping the Policy Agent**

You can stop the Policy Agent by:

- Using the operator command STOP
- Using the kill command in the z/OS shell
- Using the operator command CANCEL. Use the CANCEL command only as a last resort if the STOP or kill commands do not completely stop the Policy Agent.

**Result:** When the Policy Agent is shut down normally (KILL or STOP), if the PURGE option is configured, all QoS, IDS, and AT-TLS policies are purged from this stack. IPSec and Routing policies are not automatically purged.

The following kill command with the TERM signal will enable Policy Agent to clean up resources properly before terminating itself:

```bash
kill -s TERM pid
```

where pid is the Policy Agent process ID.
The Policy Agent process ID can be obtained using the following z/OS UNIX command:

```
ps -A
```

It can also be obtained from the /tmp/pagent.pid file. The /tmp/pagent.pid file is a temporary file created by the Policy Agent. It contains the process ID of the current invocation of the Policy Agent. This temporary file is deleted when the Policy Agent is stopped.

**Refreshing policies**

The MODIFY command may be used to interactively cause the Policy Agent to reread the configuration information and, if requested, download objects from the LDAP server. In addition to this, the Policy Agent will also accept SIGHUP signals to perform the refresh function. See the z/OS Communications Server: IP System Administrator’s Commands for more detailed information on the MODIFY command.

**Restriction:** The import policy configuration files are parsed only once. The import policies are not installed in the TCP/IP stack, so the MODIFY REFRESH and MODIFY UPDATE commands do not apply to these files.

**FLUSH and PURGE considerations**

The FLUSH/NOFLUSH and PURGE/NOPURGE parameters can be configured for each policy type supported by the Policy Agent.

**Restriction:** The import policy configuration files are parsed only once. The import policies are not installed in the TCP/IP stack, so the FLUSH and PURGE parameters do not apply to these files.

These parameters determine whether or not policies are deleted from the associated TCP/IP stack under certain conditions, as detailed in Table 43 on page 800.

Table 42 on page 799 shows where you configure these parameters for each type of local or remote policy.

<table>
<thead>
<tr>
<th>Policy type</th>
<th>Statement where configured</th>
</tr>
</thead>
<tbody>
<tr>
<td>Local Routing policies</td>
<td>Not configurable (always support FLUSH and NOPURGE)</td>
</tr>
<tr>
<td>Local IDS policies</td>
<td>IDSCfg or TcpImage/PEPInstance</td>
</tr>
<tr>
<td>Local IPSec policies</td>
<td>Not supported</td>
</tr>
<tr>
<td>Local QoS policies</td>
<td>TcpImage/PEPInstance</td>
</tr>
<tr>
<td>Local AT-TLS policies</td>
<td>TTLSConfig or TcpImage/PEPInstance</td>
</tr>
<tr>
<td>Remote policies (all types except IPSec and Routing)</td>
<td>PolicyServer or TcpImage/PEPInstance</td>
</tr>
<tr>
<td>Import policies</td>
<td>Not supported</td>
</tr>
</tbody>
</table>

**Results:**

- IPSec policies do not use these parameters. Instead, IPSec functions as though the FLUSH and NOPURGE parameters are always specified, with the exception that the FLUSH parameter has no effect when the MODIFY REFRESH command is entered.
- Parameters specified on the TcpImage/PEPInstance statement are overridden by parameters configured on other statements.
Table 43 on page 800 shows the results of using the FLUSH and PURGE parameters.

### Table 43. How Policy Agent FLUSH and PURGE are used

<table>
<thead>
<tr>
<th>Event</th>
<th>IPSec policies</th>
<th>Routing policies</th>
<th>Other policies</th>
</tr>
</thead>
<tbody>
<tr>
<td>Policy Agent start (FLUSH defined)</td>
<td>All policies are replaced in the TCP/IP stack.</td>
<td>All policies are deleted and reloaded into the TCP/IP stack.</td>
<td>All policies are deleted and reloaded into the TCP/IP stack.</td>
</tr>
<tr>
<td>Policy Agent start (NOFLUSH defined)</td>
<td>All policies are replaced in the TCP/IP stack.</td>
<td>All policies are deleted and reloaded into the TCP/IP stack.</td>
<td>All changed policies are updated in the TCP/IP stack. Deleted policies are not removed from the TCP/IP stack.</td>
</tr>
<tr>
<td>Policy Agent termination (PURGE defined)</td>
<td>TCP/IP stack policies are unchanged.</td>
<td>TCP/IP stack policies are unchanged.</td>
<td>All policies are removed from the TCP/IP stack.</td>
</tr>
<tr>
<td>Policy Agent termination (NOPURGE defined)</td>
<td>TCP/IP stack policies are unchanged.</td>
<td>TCP/IP stack policies are unchanged.</td>
<td>TCP/IP stack policies are unchanged. Deleted policies are not removed from the TCP/IP stack.</td>
</tr>
<tr>
<td>Policy Agent update (FLUSH defined)</td>
<td>If there are any changed or deleted policies, then all policies are replaced in the TCP/IP stack.</td>
<td>Any changed policies are replaced in the TCP/IP stack, and then all deleted policies are removed from the TCP/IP stack.</td>
<td>Any changed policies are replaced in the TCP/IP stack, and then all deleted policies are removed from the TCP/IP stack.</td>
</tr>
<tr>
<td>Policy Agent update (NOFLUSH defined)</td>
<td>If there are any changed or deleted policies, then all policies are replaced in the TCP/IP stack.</td>
<td>Any changed policies are replaced in the TCP/IP stack, and then all deleted policies are removed from the TCP/IP stack.</td>
<td>Any changed policies are replaced in the TCP/IP stack. Deleted policies are not removed from the TCP/IP stack.</td>
</tr>
<tr>
<td>Policy Agent refresh (FLUSH defined)</td>
<td>If there are any changed or deleted policies, then all policies are replaced in the TCP/IP stack.</td>
<td>If there are any changed or deleted policies, then all policies are deleted and reloaded into the TCP/IP stack.</td>
<td>If there are any changed or deleted policies, then all policies are deleted and reloaded into the TCP/IP stack.</td>
</tr>
<tr>
<td>Policy Agent refresh (NOFLUSH defined)</td>
<td>If there are any changed or deleted policies, then all policies are replaced in the TCP/IP stack.</td>
<td>If there are any changed or deleted policies, then all policies are deleted and reloaded into the TCP/IP stack.</td>
<td>Any changed policies are replaced in the TCP/IP stack. Deleted policies are not removed from the TCP/IP stack.</td>
</tr>
</tbody>
</table>

**Rules:**
- The TCP/IP stack results do not apply for policy client or import requester policies configured on the policy server.
- The PURGE and NOPURGE parameters have no effect on policy client or import requester policies configured on the policy server.

**Result:** When a TCP/IP stack is recycled, the result is the same as if the FLUSH parameter was specified; all active policies are reinstalled into the stack.
Switching between local and remote policies

If you dynamically switch from local policies to remote policies by adding the PolicyServer statement or a new PolicyType parameter within that statement, the FLUSH and PURGE parameters that are specified on the PolicyServer statement (or that are configured by default from the TcpImage statement) take effect, if the parameters are supported by the policy type.

Likewise, if you dynamically switch from remote policies to local policies by removing the PolicyServer statement or a PolicyType parameter from within that statement, the FLUSH and PURGE parameters that are specified on the xxxConfig statement (or that are configured by default from the TcpImage statement) take effect, if the parameters are supported by the policy type.

When the NOFLUSH parameter is used due to one of these dynamic switches, the result is that both the local and remote policies exist in the configuration; existing policies are not deleted when NOFLUSH is in effect, as shown in Table 43 on page 800.

The following examples show how switching between local and remote policies works:

• Switching from local IDS to remote IDS policies:
  1. The TcpImage statement is configured with the FLUSH parameter.
  2. The IDSConfig statement is not configured with the FLUSH or NOFLUSH parameters, so the TcpImage FLUSH value is used.
  3. The local IDS policies are read and installed.
  4. The PolicyServer statement is added with a PolicyType parameter for IDS that specifies the NOFLUSH value.
  5. The remote IDS policies are retrieved and installed.
  6. Because the NOFLUSH parameter is in effect (from the PolicyServer statement), the local IDS policies are not deleted; both the local and remote IDS policies exist.

• Switching from remote AT-TLS to local AT-TLS policies:
  1. The TcpImage statement is configured with the NOFLUSH parameter.
  2. The TTLSConfig statement is configured with the FLUSH parameter.
  3. The PolicyServer statement is configured with a PolicyType parameter for AT-TLS that specifies the FLUSH value.
  4. The remote AT-TLS policies are retrieved and installed.
  5. The PolicyType parameter for AT-TLS is removed from the PolicyServer statement.
  6. The local IDS policies are read and installed.
  7. Because the FLUSH parameter is in effect (from the TTLSConfig statement), the remote AT-TLS policies are deleted; only the local policies exist.

Result: Because the IPSec and Routing policy types always use the FLUSH value, the local and remote policies never exist at the same time.

Verifying that policies are correctly defined and functioning properly

To verify that policies are correctly defined and functioning properly, consider the following points:

• Are the policies defined correctly to the LDAP server?

  See the documentation appropriate for the LDAP server which you are using. LDAP servers usually allow you to install multiple files (LDIF), each containing different objects in the LDAP hierarchy. Structural objects higher in the directory tree must be installed before objects that are contained below them. Check for any error messages as each LDIF is installed. Some LDAP servers interpret two consecutive blank lines as end of file. Ensure that all of the objects in the LDIF have been installed by the LDAP server.

• Are the policies defined correctly to the Policy Agent?
When starting the Policy Agent, first check for any error messages issued to the console. Message EZZ8434I indicates something is wrong with the Policy Agent environment. Message EZZ8438I indicates a syntax or semantic error in the policy definitions. Messages EZZ8439I and EZZ8440I indicate a problem with the LDAP server configuration or the server itself. For more information on diagnosing Policy Agent problems, see z/OS Communications Server: IP Diagnosis Guide. Use the UNIX `pasearch` command to display policy definitions. The output from this command indicates whether or not policy rules are active, and shows the parsed results of the policy definition attributes. One thing to note is that the Policy Agent is designed to ignore unknown attributes, so misspelled attributes will result in default values being used. The `pasearch` output can be used to verify that policies are correctly defined.

- Are the import policies defined correctly for configuration file import services?

The import policy configuration files are parsed only once and always start with new policies. Any syntax or semantic errors in the import policy definitions are reported to the import requester, and result in message EZZ8438I being issued. For more information about diagnosing Policy Agent problems, see z/OS Communications Server: IP Diagnosis Guide.
Chapter 15. Quality of service

Applications and users of IP networks have different requirements for the service they receive from those networks. A network that treats all traffic as best effort does not meet the needs of such users. Service differentiation is a mechanism to provide different service levels to different traffic types based on their requirements and importance in an enterprise network. For example, it might be critical to provide Enterprise Resource Planning (ERP) traffic better service during peak hours than that of FTP or web traffic. The overall service provided to applications or users, in terms of elements such as throughput and delay, is termed Quality of service (QoS). Network service providers that need to provide different QoS levels express their business goals in Service Level Agreements (SLAs). There are two types of service in IP networks that relate to QoS. The first is Differentiated Services, which provides QoS to broad classes of traffic or users, for example all outbound web traffic accessed by a particular subnet. The second is Integrated Services, which provides end-to-end QoS to an application, by reserving resources along a data path. For z/OS Communications Server, Integrated Services is largely provided by the RSVP Agent, which implements the Resource ReserVation Protocol.

Workload distribution also relates to QoS, in terms of the throughput and delay characteristics of a given server in a sysplex. The ability to dynamically monitor server performance and affect sysplex workload distribution is an important part of the overall QoS of a sysplex. Also important is the ability to limit the set of target systems considered for sysplex routing based on network selection criteria, such as source subnet.

Differentiated Services policies

Policies for Differentiated Services (DS) are used to select and control DS traffic for selected IP servers, such as FTP server traffic. The policy administrator selects the IP traffic to be controlled by defining policy rules. These policy rules include several attributes that can be specified to identify the traffic to be managed. These attributes fall into 2 categories, general attributes and application specified attributes. General attributes can be used to identify the IP traffic of most IP applications using a variety of information, such as:

- The source or destination IPv4 or IPv6 addresses or subnets
- The source and destination ports used by the application
- The IP protocol the application is using (TCP or UDP)
- The network interface selected for the outgoing traffic
- The jobname of the application

Application specified attributes allow policy administrators to identify outgoing application IP traffic based on information that is provided and defined by an application. For example, the IBM HTTP Server Powered by Domino® provides the TCP/IP stack with the URI (Universal Resource Identifier) associated with any outgoing data being sent to a client. This allows the policy administrator to define rules that identify traffic related to specific URIs and policy actions with unique DS controls for this traffic. For example, an installation can define a policy that specifies preferential treatment of outgoing traffic related to the servicing of any URIs beginning with /product/placeorder. For more information on defining policy rules for the IBM HTTP Server Powered by Domino based on URIs, see z/OS HTTP Server Planning, Installing, and Using and the policy configuration file topic in z/OS Communications Server: IP Configuration Reference.

Any IP application using the TCP protocol can provide application specified attributes using extensions to the sendmsg() socket API. For more information, see the programming interfaces appendix in the z/OS Communications Server: IP Programmer’s Guide and Reference. Application provided attributes can be specified in 2 forms:
• Application defined data: This allows applications to provide free-form text data that can be used to classify the application's outgoing traffic in terms that should be familiar to the application's administrator (for example, URIs are provided by the IBM HTTP server).

• Application specified priority: This allows applications to associate an application priority on the outgoing IP traffic. This application priority in itself does not automatically cause the application's traffic to get preferential treatment. In order to make use of these application specified priorities the policy administrator needs to define policy rules that map these priorities to policy actions that will govern the outgoing traffic of each priority level.

Applications can pass both application defined data and application specified priorities to the TCP/IP stack. When both are specified, the administrator is free to use either or both criteria in their service policy rules. However, it is strongly recommended that any policy rules defined using the application specified attributes should also include at least one general attribute that uniquely identifies the application instance. For example, when defining rules for the HTTP server using URIs, you can help further identify the application by specifying the source port for the server or the HTTP Server's jobname. This will help ensure that unauthorized applications cannot exploit policy actions intended for the HTTP Server.

Several aspects of connection and throughput control can be specified with DS policies, including the following specifications:

• TCP connection limits
• Maximum and minimum TCP connection rates, TCP maximum delay
• Committed access bandwidth (mean rate and peak rate) control/enforcement, also known as token bucket traffic shaping
• IPv4 type of service (ToS) byte or IPv6 traffic class setting, and mapping to System z Queued Direct I/O (QDIO) device priorities and VLAN user priorities.

The above DS service attributes are enforced by the TCP/IP stack in which the DS policies are installed. For additional information on the enforcement of these attributes, see z/OS Communications Server: IP Configuration Reference.

Token bucket traffic shaping is defined using the following parameters:

• DiffServInProfileRate is the average or mean rate that you want to transmit over time. For example, 256 kilobits per second.
• DiffServInProfileTokenBucket is the burst size. This is how much data is allowed to be sent from the application to TCP/IP and still be allowed to be transmitted at the mean rate. It is suggested, if the application is not policing itself, that this burst size be at least one second's worth of data. Otherwise, if the application is sending large amounts of data at one time to TCP/IP, TCP/IP will slow that application down via congestion windows, and the mean rate may not be achieved.
• DiffServInProfilePeakRate is the highest rate that is allowed to be transmitted for a shorter interval of time. For example, though a customer might want on average only 256 Kb of data per second, they might allow a peak of 512 Kb of data for 1/4 second. The peak rate is used to control the spacing of outbound packets on the transmission line. By having a smaller peak rate, there will be longer spacing between packets, and thus less burstiness of traffic and increased efficiency. Higher peak rates result in shorter spacing and increased burstiness, which can result in lower link usage. However, some applications may require it, such as real time or video data.
• DiffServInProfileMaxPacketSize is the amount of data that will be policed at the peak cell rate. For example, if the peak rate is 512 Kb per second, and the maximum packet size is 120 Kb, TCP/IP will allow only about 10 packets of size 1492 bytes to be transmitted every .23 seconds. Again, if an application is sending large amounts of data at one time to TCP/IP, TCP/IP will enforce the peak rate, and anytime more than 10 packets are sent within .25 seconds, TCP/IP will begin to slow this TCP connection. The peak rate can be achieved over a longer period of time if the maximum packet size is entered in larger multiples of packets. However, this will cause greater burstiness as described above. For example, if the maximum packet size is entered as 240 Kb, TCP/IP will allow 20 packets in a .23 second range before enforcing slowdown.
Note that the peak rate cannot be enforced without mean rate policing. However, you can enforce mean rate without peak rate. Also, setting of these parameters depends on the type of applications and the network that carries it.

**Integrated Services policies**

Integrated Services (RSVP) policies are used to set limits on certain parameters requested by RSVP applications. These applications interact with the RSVP Agent to establish resource reservations along a network path, using the RSVP API (RAPI). The reservation requests are in the form of an entity known as a Traffic Specification, or Tspec, which consists of the following values:

- Token bucket mean rate ($r$)
- Token bucket depth ($b$)
- Peak rate ($p$)
- Minimum policed unit ($m$)
- Maximum packet size ($M$)

RSVP policies can be used to limit the values requested for ($r$) and ($b$), as well as limiting the total number of RSVP reserved flows. The RSVP service attributes are enforced by the RSVP agent which gets RSVP policies from the Policy Agent. For additional information on the enforcement, see z/OS Communications Server: IP Configuration Reference or RFC 1363.

**Sysplex distributor policies**

Sysplex distributor (SD) policies are used to specify a set of SD target nodes for a given set of traffic. For example, all traffic destined to a given port or application from a specified subnet can be assigned one group of SD target nodes, while traffic for the same port or application from another subnet can be assigned to a different group of target stacks. These policies can be used in conjunction with other sysplex distributor controls to assist in load balancing. For more information, see “Policy interactions” on page 465.

**QoS-specific Policy Agent functions**

In addition to supporting the various types of policies, the Policy Agent performs functions related to the sysplex distributor. The Policy Agent can be configured to collect network QoS performance data relevant to SD on behalf of policies defined for a target port or application, and assign a default QoS weight fraction to such policy traffic. This weight is then used by SD (in conjunction with weights assigned by the Workload Manager) to assist in load balancing decisions. This function is performed by the Policy Agent on SD target nodes within the sysplex.

The Policy Agent also supports load distribution by service level. Performance data is kept for each Policy Action (service level) that a target’s DVIPA port or application supports. A Policy Action weight fraction is generated. If available, this weight is used (instead of the default QoS weight fraction) in conjunction with the Workload Manager weight to assist in load distribution decisions for traffic assigned to this service level. If the Policy Action weight fraction is unavailable, the sysplex distributor will continue to use the default QoS weight fraction.

Another function related to policy performance is the performance collection function. When so configured, the Policy Agent collects policy performance data from the stack and caches it. This performance data is then made available to user applications through the Policy API (PAPI), for near real-time performance monitoring applications. The data are also optionally logged to a performance log file for offline performance monitoring. Sample C applications are provided to show how to use the PAPI interfaces to access performance data, and how to access and read the performance log file.
Policy performance data collected is affected by the FLUSH or NOFLUSH parameter on the Policy Agent TcpImage statement that defines the corresponding stack that is collecting the data. When FLUSH is specified, policies are deleted at the following times:

- When a new TcpImage statement is processed for the first time, including Policy Agent starting. This should not be a concern in most cases.
- When a MODIFY REFRESH command is entered.

As a result, all previously collected metrics start again from 0 when the policies are reinstalled. Conversely, policies are never deleted when NOFLUSH is specified, so performance metrics are never reset to 0.

Sysplex distributor policy performance monitoring and policy performance collection are similar in some respects but distinctly different in others:

- Sysplex distributor policy performance monitoring is actively performed by the Policy Agent. This performance monitoring is used only to assist with load balancing in a sysplex distributor environment.
- Policy performance collection is performed without regard to whether or not the Policy Agent is running in a sysplex distributor environment. Also, the Policy Agent does not actively participate in performance monitoring, only making the performance data available to user applications that perform the actual monitoring.

Policy performance data might not immediately change when changes are made to policy definitions. Some of the performance metrics are average values, and some are smoothed over several sampling intervals. As a result, when making changes to policies, some period of time will need to elapse before a new steady state is achieved.

Another function supported by the Policy Agent is to map IPv4 type of service (ToS) byte or IPv6 traffic class values to outbound interface priority values for outbound traffic. The ToS byte is also referred to as the Differentiated Services (DS) byte as an alternative definition (see RFC 2474). Note that outbound interface priority values are meaningful only for QDIO interfaces. A set of mappings can be defined to cover various ToS byte or traffic class values and map them to an appropriate interface priority. All outbound packets over the associated interfaces with a given ToS byte or traffic class value will then be assigned the corresponding priority value. ToS byte or traffic class values can also be mapped to Virtual LAN (VLAN) user priorities for propagation over LANs directly connected through the OSA-Express feature.

Note: Coding the virtual LAN (VLAN) user priority causes a frame to be sent out based on the IEEE 802.1Q specification, which establishes a standard method for tagging Ethernet frames with VLAN priority and membership information. Specifically, a VLAN priority-tagged frame is used to convey packet priority to the switches; it has a value of NULL for VLANID. A full VLAN-tagged frame contains both the priority and non-null VLANID. If you have switches in your network that do not support the IEEE 802.1Q standard or that are not properly configured for these types of frames, the frames might be dropped by the switch.

Sysplex distributor policy performance monitoring configuration

Before activating the sysplex distributor policy performance monitoring function, see “Policy interactions” on page 465 for information on workload balancing and policy interactions with sysplex distributor.

The following example illustrates how to activate the policy performance monitoring function for sysplex distributor.

Note: This function is activated on SD target servers and is used to monitor the performance of outbound traffic being serviced by the target servers. The goal is to detect TCP traffic that exceeds defined thresholds for dropped packets or time-outs, and derive a default QoS weight fraction for the target server. This default QoS weight fraction is then used to reduce the WLM weight assigned to the target servers, so that the SD distributing stack can take QoS performance into account.

The following statements apply to the example in this topic:

- The policy performance monitoring sampling interval is 60 seconds.
• Policy Agent assigns a loss ratio weight fraction of 25% when the TCP loss ratio (dropped packets to total packets) starts to exceed 2%.
• The loss ratio weight fraction is increased to 50% when the loss ratio starts to exceed 4%, continuing in this manner up to the maximum loss ratio weight fraction of 95%.
• In a similar manner, a TCP timeout weight fraction of 50% is assigned when the timeout ratio starts to exceed 5%, increasing up to a maximum timeout weight fraction of 100%.
• The loss ratio weight fraction and TCP timeout weight fraction are added together to form a single default QoS weight fraction for the target server, up to a maximum of 100%. When the Traffic Regulation policy connection limit reaches constrained threshold (90%), the default QoS weight fraction is set to 100% and forces SD to route requests to other target nodes with better routing weights.
• The default QoS weight fraction is used at the SD distributing stack to reduce the WLM weight. For example, if the WLM weight is 40, a weight fraction of 50% results in the weight being reduced to 20.
• The traffic to be monitored must be represented by at least one Differentiated Services policy defined for the target application (in this example a policy is defined for Telnet).
• An additional Policy Action weight fraction is calculated for a target’s DVIPA/Port if there are any active connections to the target using that service level.

The Policy Action weight fraction is calculated as the largest of three fractions:

- The number of active connections to this target DVIPA/Port will be compared with the maximum connections allowed for this Policy action.
  - When the number of active connections reaches 50% of maximum connections, then the Policy Action weight fraction will be set to MAX (50%, current calculated value).
  - When the number of active connections reaches 65% of maximum connections, then the Policy Action weight fraction will be set to MAX (85%, current calculated value).
  - When the number of active connections reaches 80% of maximum connections, then the Policy Action weight fraction will be set to 100%.
- The throughput rate for this timer interval will be calculated and compared to the DiffServ mean rate of this Policy action. If the throughput rate is greater than 85% of the DiffServ mean rate, the average throughput rate per connection will be calculated. If the throughput rate per connection is less than the DiffServ min rate, the minimum throughput requirement per connection is not being met and the Policy Action weight fraction will be set to 100%.
- The default QoS weight fraction.

• Only one policy rule and policy action are defined here.

As a result, only Telnet QoS performance information is monitored by the Policy Agent for sysplex distributor to route incoming Telnet connections to this target node relative to other target nodes which presumably can also accept Telnet requests.

```
PolicyPerfMonitorForSDR enable {
  samplinginterval 60
  LossRatioAndWeightFr 20 25
  TimeoutRatioAndWeightFr 50 50
  LossMaxWeightFr 95
  TimeoutMaxWeightFr 100
  MaxConnWeightFr 50 65 80
}

policyAction telnetGold {
  MinRate 500 # Provide minimum rate of 500 Kbps.
  OutgoingTOS 10100000 # the TOS value of outgoing telnet packets.
}

policyRule targetelnet {
  ProtocolNumberRange 6
  SourcePortRange 23
}
```
Policy performance collection configuration

The following example shows how to activate the policy performance collection function. Policy performance data for all active policies is maintained by the TCP/IP stack. This function allows this data to be collected and made available for policy performance monitoring applications. The following statements apply to the example in this topic:

• Performance data is collected for both rules and actions. Action data is an aggregate of the data for the rules that refer to the action. For policies that have a single action per rule, the performance data will be the same for both the rule and action.
• The default minimum sampling interval is 30 seconds. This is the minimum value accepted for the acceptableCachedTime parameter on the PAPI papi_get_perf_data() function that gets performance data.
• Performance data will be logged to the file /u/user10/perflog, based on a sampling interval of 60 seconds.
• The number of performance log files maintained is 10, each of which is the default 300 kilobytes in size. In this example, the log files will be named assuming a stack name of TCPCS:

- /u/user10/perflog.TCPCS
- /u/user10/perflog.TCPCS.1
- /u/user10/perflog.TCPCS.2
- …
- /u/user10/perflog.TCPCS.9

• Each performance data record is 232 bytes, so a file size of 300 kilobytes can contain 1324 records. Because 10 files are maintained, the total set of log files can contain 13240 records. Assuming that 50 policy rules and actions exist in the configuration, this means that the set of log files will wrap in approximately 4.4 hours, according to the following formula:

\[
\text{number of records (13240)} / \text{number of policies (50)} = \text{number of refresh cycles (264)}
\]

\[
\text{number of refresh cycles (264)} \times \text{refresh interval in minutes (1)} = 264 \text{ minutes worth of data}
\]

IPv4 type of service or IPv6 traffic class mapping configuration

There are two mappings provided by the SetSubnetPrioTosMask statement:

• IPv4 type of service (ToS) or IPv6 traffic class to device priority
  Quality of service (QoS) support in z/OS Communications Server allows the IPv4 ToS byte, also known as the Differentiated Services (DS) field, or the IPv6 traffic class to be set for outbound IP packets according to defined policies managed by the z/OS Communications Server UNIX Policy Agent. When IP packets are sent out over QDIO devices, the ToS/DS or traffic class value is mapped to a QDIO priority value. Device priority values are 1-4, where 1 is the highest priority.

• IPv4 ToS or IPv6 traffic class to VLAN user priority
  ToS/DS or traffic class values can be mapped to user priorities for directly attached LANs using the OSA-Express feature in QDIO mode. VLAN user priority values are 0-7, where 7 is the highest priority. This allows assigned user priorities to be propagated through such networks, resulting in no loss of priority information for data being served by z/OS.

See z/OS Communications Server: IP Configuration Reference for more detail on these statements.
The following example shows a mapping of various ToS byte or traffic class values to associated interface priority values. Note that the mapping can be applied to individual interfaces or all interfaces:

- The first example defines a mapping for a specific interface. Note that the specified interface must be a valid interface specified in the HOME list. The second example shows a different mapping for all other interfaces.
- The subnet mask defines the bits in the ToS byte or traffic class that are significant. These examples use the leftmost 3 bits.
- The first example shows a set of mappings defining the complete set of ToS byte or traffic class values and the device and VLAN user priorities to be assigned for each value.
- The second example shows a set of mappings defining the complete set of ToS byte or traffic class values and the device priority to be assigned for each value.

```
SetSubnetPrioTosMask
{
  SubnetAddr 10.10.1.5
  SubnetTosMask 11100000
  PriorityTosMapping 1 11100000 7
  PriorityTosMapping 1 11000000 7
  PriorityTosMapping 2 10100000 6
  PriorityTosMapping 2 10000000 5
  PriorityTosMapping 3 01100000 3
  PriorityTosMapping 4 00100000 2
  PriorityTosMapping 4 00000000 0
}
SetSubnetPrioTosMask
{
  SubnetTosMask 11100000
  PriorityTosMapping 1 11100000
  PriorityTosMapping 1 11000000
  PriorityTosMapping 1 10100000
  PriorityTosMapping 1 10000000
  PriorityTosMapping 2 01100000
  PriorityTosMapping 2 01000000
  PriorityTosMapping 3 00100000
  PriorityTosMapping 4 00000000
}
```

### Options for configuring QoS

You configure QoS using a set of configuration statements and parameters coded into a flat file, which is parsed by the Policy Agent to establish the QoS policy for each TCP/IP stack. In a complex environment, this file can become large. For this reason, there are two alternatives for creating the Policy Agent files.

**Option 1: Use the IBM Configuration Assistant for z/OS Communications Server**

The IBM Configuration Assistant for z/OS Communications Server, an optional GUI-based tool, provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the IBM Configuration Assistant for z/OS Communications Server to generate the Policy Agent files.

The IBM Configuration Assistant for z/OS Communications Server is a z/OS Management Facility (z/OSMF) task. z/OSMF provides a web browser interface for a variety of z/OS system management functions. When you invoke the IBM Configuration Assistant for z/OS Communications Server in z/OSMF, the IBM Configuration Assistant for z/OS Communications Server runs natively in the z/OS system and you can access it through a web browser.

Through a series of wizards and online help panels, you can use the IBM Configuration Assistant for z/OS Communications Server to create QoS configuration files for any number of z/OS images with any number of TCP/IP stacks per image. Using the IBM Configuration Assistant for z/OS Communications Server, there are four types of reusable objects:

- Traffic descriptors that define the local application by describing the TCP traffic with ports or identifying the application using its job name.
• Priority levels that define the level of network priority or type of service (ToS).
• Traffic shaping levels that define settings to enforce specific traffic thresholds.
• Requirement maps that map traffic descriptors to priority levels and traffic shaping levels. A single requirement map should contain a complete set of QoS requirements that will govern the level of service for multiple IP traffic types.

For each TCP/IP stack, you select a requirement map that provides QoS for the stack.

The IBM Configuration Assistant for z/OS Communications Server comes with a number of IBM-supplied traffic descriptors, priority levels, traffic shaping levels and requirement maps that are easily applied, or you can use the IBM-supplied definitions as the basis for your own set of reusable objects.

The IBM Configuration Assistant for z/OS Communications Server can dramatically reduce the amount of time that is required to create QoS policy files, contributing to ease of configuration and maintenance. Because of the inherently complex nature of z/OS, using the GUI can help you ensure that you have a consistent and easily manageable interface for implementing QoS.

This information primarily describes option 2, manual configuration. However, if you are using the IBM Configuration Assistant for z/OS Communications Server, reading this information will help you understand security concepts and the relationship between Policy Agent and QoS function.

**Option 2: Manual configuration**

You can manually create the QoS policy configuration files by coding all of the required statements in a file. There are a large number of configuration options provided by QoS policy statements that permit advanced users to carefully fine-tune QoS policy on a per-stack basis. This information describes the procedure for creating a QoS policy by manually creating and editing the configuration files. For details about the QoS policy statements, see z/OS Communications Server: IP Configuration Reference.

**Specifying the QoS configuration file based on Policy Agent role**

The Policy Agent can act as a policy server, a policy client, or neither. For more information on these different roles, see “Policy types and infrastructure overview” on page 761. Regardless of which option is used to configure QoS policies, the resulting configuration files need to be specified using different statements, depending on the role of the Policy Agent.

• If you are using the Policy Agent as a policy client that retrieves QoS policies from the policy server, specify the configuration files using the DynamicConfigPolicyLoad statement on the policy server.
• If you are using the Policy Agent as a policy client, but the policy client does not retrieve QoS policies from the policy server, specify the configuration files using the QOSConfig statement on the policy client, or configure the QoS policies directly in the image file specified on the TcpImage statement.
• If you are not using a policy client/policy server environment, specify the configuration files using the QOSConfig statement on the single Policy Agent, or configure the QoS policies directly in the image file specified on the TcpImage statement.

When specifying configuration files, keep in mind where the files should exist, based on the role of the Policy Agent.

**Defining policies in a Policy Agent configuration file**

Configure the following statements in the configuration file to define policies:

• PolicyAction
• PolicyRule

See z/OS Communications Server: IP Configuration Reference for more information about these statements.

The following subtopics contain examples of these tasks.
**Note:** These examples are for illustrative purposes only. The policies deliberately use a wide variety of attributes, and they do not necessarily represent real-world usage. Some examples show continued and indented statements that were modified to fit within the margin and therefore are not an actual representation of correct syntax.

**Differentiated Services policy examples**

The goal of this Differentiated Services policy is to map a subset of the traffic outbound from an FTP server.

This policy is identified as a Differentiated Services policy by the PolicyScope DataTraffic attribute on the PolicyAction statement, as well as the use of several DS-only attributes.

The following statements apply to the example in this topic:

- The policy rule selects traffic originated by ports in the range 20-21 (FTP outbound data connection uses port 20) from the source address 200.50.23.11.
- The policy rule is active on weekdays between 6 a.m. and 10 p.m. local time, between the dates 7/1/2000 and 7/1/2005.
- The policy action specifies that the ToS byte be set to '10000000' for traffic that conforms to this policy.
- The action establishes a *token bucket* traffic conditioner with a mean rate of 256 kilobits per second, a peak rate of 512 kilobits per second, and a burst size of 64 kilobytes. Any traffic that exceeds these specifications will be sent as *best effort*, with an accompanying ToS byte of '00000000'.

```plaintext
PolicyRule                               diffServ
{                                        
  ProtocolNumberRange                   6
  SourceAddressRange                    200.50.23.11
  SourcePortRange                       20-21
  PolicyActionReference                 tokenbucket
  PolicyRulePriority                    10
  ConditionTimeRange                    20000701000000:20050630235959
  DayOfMonthMask                        11111111111111111111111111111111
  DayOfWeekMask                         0111110
  TimeOfDayRange                        06:00-22:00
}                                        
PolicyAction                             tokenbucket
{                                        
  PolicyScope                           DataTraffic
  OutgoingTOS                           100000000
  DiffServInProfileRate                 256       # 256 Kbps
  DiffServInProfileTokenBucket          512       # 512 Kbits
  DiffServInProfilePeakRate             512       # 512 Kbps
  DiffServInProfileMaxPacketSize        120       # 120 Kbits
  DiffServOutProfileTransmittedTOSByte  00000000
  DiffServExcessTrafficTreatment        BestEffort
}                                        
```

The goal of this policy is to ensure that outgoing data that match the specified attributes will be assigned a QoS service level defined in action "interactive1".

The following statements apply to the example in this topic:

- This rule will match traffic only on TCP connections (protocol 6) with a source port of 80 (i.e. HTTP server) and application defined data beginning with the string "/catalog".
- Because we are dealing with HTTP traffic, this rule is basically indicating that all outgoing traffic associated with a URI that begins with "/catalog" should be managed using the DS characteristics specified in the "interactive1" policy action.

```plaintext
PolicyRule          web-catalog       # web catalog traffic
{                   
  protocolNumberRange 6
  SourcePortRange    80
  ApplicationData /catalog
  policyActionReference interactive1
}                   
PolicyAction      interactive1
```
RSVP policy example

The goal of this RSVP policy is to establish limits on resource reservations requested by RSVP applications using the RSVP API (RAPI) interface. The policy is identified as an RSVP policy by the PolicyScope attribute on the PolicyAction statement, as well as the use of RSVP-only attributes.

The following statements apply to the example in this topic:

- The policy rule selects traffic from source ports in the range 8000 to 8001, with a protocol ID of 6 (TCP).
- The DataTraffic policy action specifies that the ToS byte be set to 01100000 for differentiated service traffic that conforms to this policy. Essentially, any traffic sent by the target application without an RSVP reservation in place will use this policy action. After an RSVP reservation is in place, the RSVP action gets used.
- The RSVP policy action specifies that the ToS byte be set to 01100000 while an RSVP reservation is in place. It also limits the type of RSVP service requested by RSVP applications to Controlled Load. Applications requesting Guaranteed service are downgraded to using Controlled Load service. In addition, the action limits the mean rate and token bucket size to 50000 bytes per second and 6000 bytes, respectively. These values are requested by RSVP applications in the traffic specification, or Tspec.
- The action also limits the number of active RSVP flows that map to this policy to 10.

Sysplex distributor policy example

The goal of this sysplex distributor policy is to limit the number of SD target stacks for inbound Telnet traffic. The policies are identified as SD policies by the ForLoadDistribution TRUE attribute on the PolicyRule statement. The corresponding policy on the target is also shown.

The following statements apply to the example in this topic:

- Separate policies are defined on the sysplex distributor distributing and target stacks.
- The policy rules select incoming Telnet connection requests.
- The selected target stack will be based on WLM information and QoS information if activated at the target stacks.
- The rule (disttelnet) is coded on the distributing stack to select inbound traffic destined to the Telnet server.
- The rule (targtelnet) is coded on the target stack to select outbound data from the Telnet server.
• If none of the specified target stacks is available to service incoming requests (either the node is down or the Telnet server is not active), then sysplex distributor will distribute the requests to any available target stack.

**Result:** If the OutboundInterface 0.0.0.0 statement (for IPv4) and the OutboundInterface :: statement (for IPv6) are not present, and the defined target stacks are not available, sysplex distributor rejects the request.

```plaintext
policyAction        telnetGold
{                          # Provide minimum rate of 500 Kbps.
MinRate        500
OutgoingTOS    10100000  # the TOS value of outgoing telnet packets.
outboundinterface  129.100.11.1
outboundinterface  129.100.21.1
outboundinterface  129.200.12.1
outboundinterface  129::1B0D:13F0
outboundinterface  0.0.0.0
outboundinterface  ::
}
```

```plaintext
classRule           disttelnet
{                          # the TOS value of outgoing telnet packets.
ProtocolNumberRange     6
DestinationPortRange    23
PolicyRulePriority      20
policyactionreference   telnetGold
ForLoadDistribution     TRUE
}
```

```plaintext
classRule           targtelnet
{                          # the TOS value of outgoing telnet packets.
ProtocolNumberRange     6
SourcePortRange         23
PolicyRulePriority      20
policyactionreference   telnetGold
ForLoadDistribution     FALSE
}
```

**Notes:**

1. The ApplicationName attribute is valid only for a target rule and should not be coded on a distributor rule because the application name determined for inbound traffic (which is always the case on a distributor) will always be the stack's TCP jobname.

2. If you are using Telnet with multiple stacks in conjunction with the sysplex distributor, see Chapter 11, “Accessing remote hosts using Telnet,” on page 539 for more information.

---

**Defining policies using LDAP**

For information about defining QoS policies using LDAP, see “Defining QoS policies using LDAP” on page 1359.

---

**RSVP**

Resource ReSerVation Protocol (RSVP) is a protocol that provides a mechanism to reserve resources in support of Integrated Services. The z/OS UNIX RSVP agent provides the following services on behalf of applications that want to use Integrated Services:

- An RSVP API (RAPI) that allows applications to explicitly request RSVP services. Using RAPI, applications indicate their intent to send or receive data, describe the characteristics of the data traffic and request that RSVP reserve resources along the data path to provide a given QoS to one or more traffic flows. For more information about RAPI, see z/OS Communications Server: IP Programmer's Guide and Reference.
- Mapping of IP ToS settings to RSVP traffic, using policies defined for RSVP.
- Support for VIPA addresses as well as real IP addresses.
• Communication with other RSVP agents on hosts and routers in the network to communicate application resource reservation requests.

Network administrators can use the z/OS UNIX Policy Agent to define RSVP-specific policies. These policies can be used to limit the parameters of application-requested resource reservations, provide ToS mappings for RSVP traffic, and limit the number of traffic flows that can use RSVP services simultaneously.

RSVP is designed to be implemented on both end systems (hosts) and routers. Different functions are provided by RSVP in these two environments. The z/OS RSVP agent is supported as a host RSVP implementation only. It can communicate with router RSVP implementations, but is not itself supported as such. For more information about RSVP, see RFC 2205.

Configuring the RSVP agent

To configure the RSVP agent, update the configuration file to specify RSVP agent operational parameters using the LogLevel, TcpImage, Interface and RSVP statements. See z/OS Communications Server: IP Configuration Reference for detailed information about the statements.

To start the RSVP agent, you must first authorize the RSVP Agent using the security product. See SEZAINST(EZARACF) for SAF considerations for started tasks.

The following example is an RSVP configuration file. This example:
• Runs the RSVP Agent on the stack selected using the standard resolver search order, because a TcpImage statement is not configured.
• Disables RSVP processing on interface 10.11.12.13, while enabling it for all other interfaces.
• Disables traffic control on interface 200.1.1.1. This means that no reservations will be made on this interface.
• Allows a maximum of 50 active RSVP flows per interface.

```
Interface 10.11.12.13 Disabled
{} Interface 200.1.1.1 Enabled
{ TrafficControl Disabled
} Interface Others Enabled
{ Rsvp All Enabled
{ MaxFlows 50
}
```

Starting and stopping RSVP

RSVP can be started from the z/OS shell or as a started task.

The RSVP agent uses the following search order to locate the configuration file (highest priority is listed first):
• z/OS UNIX file or MVS data set specified by the -c startup option. The syntax for a z/OS UNIX file is '/dir/file', and the syntax for an MVS data set is "'/MVS.DATASET.NAME'".
• z/OS UNIX file or MVS data set specified with the RSPVD_CONFIG_FILE enviroment variable.
• /etc/rsvpd.conf z/OS UNIX file.
• 'hlq.RSVPD.CONF' MVS data set.

Note: If this file is not present, RSVP is enabled on all network interfaces with default parameters.

When starting from the shell, note that the RSVP executable file is in the /usr/lpp/tcpip/sbin directory. There is also a link from the /usr/sbin directory. Make sure your path statement (in the profile) contains either the /usr/sbin or /usr/lpp/tcpip/sbin directory.
Use the S RSVPD command on an MVS console or SDSF to start RSVP as a started task. A sample procedure is shipped in member EZARSVPP in SEZAINST.

The /tmp/rsvpd.pid.tcpname is a temporary RSVP daemon pid file that the RSVP daemon creates. This file contains the process ID of the current invocation of the RSVP daemon.

**Restrictions:**

- If /tmp/rsvpd.pid.tcpname is a symbolic link, it must have an owning UID or GID that matches the EUID or EGID that is assigned to the RSVP daemon.

- If /tmp/rsvpd.pid.tcpname is a hard link or the target of a hard link, users that are outside the owner or group of the directory in which /tmp/rsvpd.pid.tcpname is stored cannot have write access to the directory. Additionally, write access to /tmp/rsvpd.pid.tcpname must be limited to the owning UID or group, for example, --w--w----permissions.

RSVP can be stopped using the cancel command (C RSVPD) or using the kill command in the z/OS shell. The following kill command with the TERM signal will enable RSVP to clean up resources properly before terminating itself:

```
kill -s TERM pid
```

where `pid` is the RSVP process ID.

The RSVP process ID can be obtained using the following z/OS UNIX command:

```
ps -A
```

It can also be obtained from the /tmp/rsvpd.pid.tcpname file. See z/OS Communications Server: IP Configuration Reference for more information.

---

**SNMP Network SLAPM2 (nslapm2) performance monitor**

The SLAPM2 subagent provides information about defined service policies and performance data for applications that are mapped to those policies. Statistics are retrieved by this subagent and monitored for possible Network SLAPM2 performance deviations. For more information about the Network-SLAPM2 MIB, see `usr/lpp/tcpip/samples/slapm2.mi2`.

**Configuring the Network SLAPM2 subagent**

The z/OS CS Network SLAPM2 subagent allows network administrators to retrieve data and determine if the current set of Network SLAPM2 policy definitions are performing as needed or if adjustments need to be made. Before starting the Network SLAPM2 subagent, some basic operational characteristics of the Network SLAPM2 subagent need to be configured.

**Procedure**

Perform the following steps to configure the Network SLAPM2 subagent:

1. Configure the Network SLAPM2 subagent security authorization.

   For the subagent to retrieve performance monitor data from the Policy Agent, the Network SLAPM2 subagent must have superuser authority or security product authority in the SERVAUTH class.

   These profiles can be defined by TCP/IP stack and policy type as follows, where `sysname` is the system name defined in the sysplex, `TcpImage` is the TCP name for policy information that is being requested, and `ptype` is the policy type (QOS) that is being requested:

   ```
   EZB.PAGENT.sysname.TcpImage.ptype
   ```

   Wildcarding is allowed on segments of the profile name.

   If SERVAUTH class is absent (not RACLIST) or profiles are absent for the subagent's request (TcpImage and policy type), permission is denied and data is not returned.
If SERVAUTH class is active, profiles are present for the subagent's request (TcpImage and policy type), and an MVS user is defined for all profiles, permission is granted and data is returned.

If SERVAUTH class is active, profiles are present for the subagent's request (TcpImage and policy type), and an MVS user is not defined for all profiles, permission is refused and data is not returned.

For the sample commands needed to create the profile name and permit users to it, see the EZARACF sample in SEZAINST.

2. Configure the Policy Agent as follows:

   • Configure QoS policy rules and QoS policy actions in Policy Agent. The Network SLAPM2 subagent keeps statistics only for active QoS policies. For details, see “Steps for configuring the Policy Agent” on page 780.
   • Configure PolicyPerformanceCollection in Policy Agent. The PolicyPerformanceCollection statement for rules needs to be enabled to retrieve performance monitoring information from Policy Agent for the Network SLAPM2 Subagent. For details on the PolicyPerformanceCollection statement, see “Policy performance collection configuration” on page 808.

3. Configure and start the SNMP agent. For details, see “Step 1: Configure the SNMP agent” on page 1214.

### Starting and stopping the Network SLAPM2 subagent

Before you start the Network SLAPM2 subagent, the following applications need to be started and initialized:

- Policy Agent - For details, see “Starting and stopping the Policy Agent” on page 795.
- SNMP agent - For details, see “Start the SNMP agent” on page 1224.

The Network SLAPM2 subagent can be started from the z/OS shell or as a started task.

- When starting from the shell:

  The Network SLAPM2 subagent executable file (nslapm2) is in /usr/lpp/tcpip/bin. There is also a link from /bin. Make sure your PATH statement (in the profile) contains either /bin or /usr/lpp/tcpip/bin.

  The Network SLAPM2 subagent requires access to one or more DLLs at run time. The LIBPATH environment variable needs to be set to include the /usr/lib directory, which normally includes all the required DLLs.

  Export the LIBPATH environment variable before starting the subagent. This is best accomplished in /etc/profile or in .profile in the HOME directory. For example:

  ```
  export LIBPATH=/usr/lib
  ```

  The following command is an example:

  ```
  nslapm2 -d 3 -t 1800 -c special -P 5000
  ```

  The command above starts the Network SLAPM2 subagent with the following characteristics:

  - Connect to the SNMP agent using a community name of special and a port of 5000.
  - The debugging level is set to 3, to log the following debugging messages to syslogd:
    - Trace Network SLAPM2 subagent error and system console messages
    - Trace Network SLAPM2 subagent warning messages
  - The MIB table cache time is set to 30 minutes.

- When starting as a started task:

  Use the S NSLAPM2 command on an MVS console or SDSF. A sample procedure is shipped in member EZAPAGSB in SEZAINST.
- Specify LIBPATH using the ENVAR parameter on the PARM statement in the started procedure. For example:

```c
// PARM=('POSIX(ON) ALL31(ON)',
// 'ENVAR("LIBPATH=/usr/lib")'/)
```

- Export the LIBPATH environment variable in a file specified with the STDENV DD statement. For example:

```c
//STDENV DD PATH='/etc/nslapm2.env',PATHOPTS=(ORDONLY)
```

In the `/etc/nslapm2.env` file:

```c
LIBPATH=/usr/lib
```

For more information on specifying run-time options, see z/OS Language Environment Programming Guide. For details on setting the LIBPATH environment variable, also see z/OS UNIX System Services Command Reference.

The `/tmp/nslapm2.tcpname.pid` is a temporary NSLAPM2 subagent pid file that the Network SLAPM2 subagent creates. This file contains the process ID of the current invocation of the Network SLAPM2 subagent.

**Restrictions:**

- If `/tmp/nslapm2.tcpname.pid` is a symbolic link, it must have an owning UID or GID that matches the EUID or EGID that is assigned to the Network SLAPM2 subagent.

- If `/tmp/nslapm2.tcpname.pid` is a hard link or the target of a hard link, users that are outside the owner or group of the directory in which `/tmp/nslapm2.tcpname.pid` is stored cannot have write access to the directory. Additionally, write access to `/tmp/nslapm2.tcpname.pid` must be limited to the owning UID or group, for example, `--w--w----permissions`.

The Network SLAPM2 subagent can be stopped using the `stop` command (P NSLAPM2), or using the `kill` command in the z/OS shell. For example, the following `kill` command with the TERM signal, where `pid` is the `nslapm2` process ID, enables the Network SLAPM2 subagent to clean up resources properly before terminating itself:

```c
kill -s TERM pid
```

The `nslapm2` process ID can be obtained using the following z/OS UNIX command:

```c
ps -A
```

## Verification

To verify that policies are correctly defined and functioning properly, consider the following points:

- Are the policies installed in the TCP/IP stacks?
- Is the expected traffic mapping to the correct policies?
- Are the sysplex distributor policy functions working correctly?
- Does anything need to be tuned?

The following subtopics provide more details about these considerations.

### Verifying that the policies are installed in the TCP/IP stacks

Use the `Netstat SLAP/-j` command to display QoS policy statistics. This command displays statistics for only active (installed) QoS policies, so it can be used to verify the correct policies are installed, even if all the statistics are 0. Because the Policy Agent can install policies on multiple stacks, issue this command on each stack to verify the correct set of QoS policies is installed.
Verifying that the expected traffic is mapping to the correct QoS policies

While connections are active, use the Netstat ALL/-A command to display details about the active connections. One piece of information displayed is the policy rule name. If this name is blank, then the traffic is not mapped to any active rule. Also, use the Netstat SLAP/-j command to display QoS policy statistics. The output shows the time that each policy was last mapped to traffic, and accumulated statistics for each policy. Monitor these values over time to verify that new traffic is mapping as expected.

Note: The values displayed by the Netstat SLAP/-j commands can wrap around to 0. If some of the values do not seem correct (for example, total out bytes less than total out bytes in profile), then wrapping has probably occurred.

Verifying that the sysplex distributor policy functions are working correctly

To verify that the distributor is using the expected service levels when deciding how to distribute traffic to each DVIPA/Port target, use the Netstat VDPT/-O DETAIL command on the distributing stack. The following QoS related information will be displayed for each DVIPA/Port target:

- WLM weight unmodified by QoS
- Modified WLM/QoS aggregate weight, identified by *DEFAULT*
- Modified WLM/QoS service level weights, identified by service level name

To verify that active connections distributed to DVIPA/Port targets are using the expected service level, use the Netstat VCRT DETAIL command on the distributing stack. This will display the following policy related information:

- PolicyRule: the policy rule that the distributor used in selecting the policy action for this connection.
- PolicyAction: the policy action that this connection is currently using. If PolicyAction is specified by *NONE*, then the distributor is using the *DEFAULT* fraction to distribute this connection.

See z/OS Communications Server: IP Diagnosis Guide for more information.

Monitoring performance and tuning policies

Poor performance, such as low throughput, long response times, and so on, might be suddenly and consistently experienced by a certain set of users or applications. Also, traps might be generated by the Network SLAPM2 subagent. When this happens, the problem might be the way the QoS policy is defined for the corresponding set of users or applications.

For example, the IPv4 ToS/DS or IPv6 traffic class value might be set incorrectly to a lower QoS level than is intended, for example, medium or low priority instead of high priority. It is important to remember that given a fixed amount of network resources, changing some traffic demand from a lower to higher QoS level will mean that other traffic demands will be affected. Therefore, use care to ensure that in attempting to meet one set of QoS requirements, different or worse problems do not result.

Another cause for poor performance might be in the way the bandwidth allocation defined via the DiffServ token bucket parameters, or TCP maxrate or minrate, is not adequate to accommodate the traffic demand. Yet another possibility might be that either network or the server capacity is not adequate to handle the traffic demand. This is evident when a majority of users or applications do not have their QoS requirements met. When this happens, the network planning process must be revisited.

For more information, see “Using the Network SLAPM2 MIB to monitor policies” on page 819.

Using pasearch

Use the pasearch command to display policy details. This command displays both active (installed in the stack) and inactive policies. Various parameters can be specified to filter the results, for example to display only policies for certain stacks, only QoS policies, only policy names, or only a single policy specified by name. See z/OS Communications Server: IP System Administrator's Commands for the complete syntax and sample output for pasearch.
Using the Network SLAPM2 MIB to monitor policies

The Network SLAPM2 subagent provides information about service policies and performance data for applications mapped to those policies through the slapm2PolicyRuleStatsTable.

Note: The Network SLAPM2 subagent can be used to monitor Differentiated Services policies.

slapm2PolicyRuleStatsTable
Provides statistics on a per policy rule basis.

The Network SLAPM2 subagent also supports performance monitoring with the slapm2PRMonTable object. Entries are created in the monitor table to establish the wanted criteria for monitoring. The following level of monitoring is provided:

Aggregate
Monitoring is performed based on the aggregate of all TCP or UDP applications that are mapped to one or more service policies.

Three types of monitoring are provided for measuring application performance:

TCP round-trip time
The current TCP round-trip time of applications are compared to the threshold values established in the monitor table entry. If the current rates exceed the high threshold or go below the low threshold, an SNMP trap is sent if traps are enabled.

TCP packets retransmit ratio
The current TCP packets retransmit ratios of applications are compared to the threshold values established in the monitor table entry. If the current rates exceed the high threshold or go below the low threshold, an SNMP trap is sent if traps are enabled.

Average accept queue delay
The current average accept queue delay of applications are compared to threshold values established in the monitor table entry. If the current rates exceed the high threshold or go below the low threshold, an SNMP trap is sent if traps are enabled.

For more details about how to make the various monitoring calculations, see the NETWORK-SLAPM2-MIB in the sample file slapm2.mi2 in the /usr/lpp/tcpip/samples directory.

When SNMP traps are enabled, and a not achieved trap is sent as described above, a corresponding okay trap is sent when the traffic again conforms to the boundaries established in the monitor table entry.

For example, suppose the slapm2PRMonTcpRttDelayHigh value is set to 2 seconds and the slapm2PRMonTcpRttDelayLow value is set to 1 second. If the TCP round-trip delay rises above 2 seconds, a not achieved trap is sent. If the TCP round-trip delay then drops below 1 second, an okay trap is sent to indicate the problem has been resolved. However, if the row becomes inactive before conforming to the established boundaries, an okay trap is never sent, because this removes monitoring for this entry.

The following traps are used to monitor table administration:

Policy deleted
A slapm2PolicyRuleDeleted trap is sent when an entry is deleted from the slapm2PolicyRuleStatsTable, if slapm2PolicyDeletedTrapEnabled is enabled(1).

Monitor deleted
A slapm2PolicyRuleMonDeleted trap is sent when a slapm2PRMonEntry is deleted, if the value of slapm2PolicyDeletedTrapEnabled is enabled(1).

Creating monitor table entries and enabling SNMP traps
Several MIB objects are used when establishing monitor table entries and when configuring whether and how often traps are sent. To establish monitor table entries, set the following MIB object variables. Most of these objects have default values, so you might be able to achieve the wanted monitoring using only a subset of the objects.
slapm2PRMonTcpRttDelayHigh, slapm2PRMonTcpRttDelayLow
Establishes the threshold values for the average TCP round-trip time. The minimum and maximum rates are in units of milliseconds.

slapm2PRMonTcpReXmitHigh, slapm2PRMonReXmitLow
Establishes the threshold values for the TCP packets retransmit ratio. The minimum and maximum rates are in tenths of a percent units.

slapm2PRMonTcpAcceptQDelayHigh, slapm2PRMonTcpAcceptQDelayLow
Establishes the threshold values for the average accept queue delay. The minimum and maximum rates are in units of milliseconds.

slapm2PRMonRowStatus
This object allows entries to be created and deleted in the slapm2PRMonTable.

In addition, the following MIB objects are used to control the generation of traps:

slapm2PRMonTrapEnable
Indicates whether slapm2PolicyRuleMonNotOkay and slapm2PolicyRuleMonOkay notifications should be generated for this conceptual row.

slapm2PRMonTrapFilter
The purpose of this object is to suppress excessive slapm2PolicyRuleMonNotOkay notifications. A monitored quantity must exceed its high threshold for the number of consecutive intervals indicated by this object for a notification to be generated. The length of the intervals is specified by the slapm2PolicyMonInterval object.

Creating the monitor table index

When you create monitor table entries, specify the appropriate index value. The index is composed of:

• slapm2PRMonOwnerIndex
• slapm2PolicyRuleIndex

The OwnerIndex is expressed in the following format, where character is in ASCII decimal form:

```
length.character.character...```

For example, the value u1 is expressed as 2.117.31. The PolicyRuleIndex that maps to the policy name value is the index into the slapm2PolicyRuleTable.

The Network SLAPM2 subagent creates an entry in the slapm2PolicyRuleTable to represent a policy rule. The index value for this entry is arbitrary and assigned by the subagent. Corresponding entries in the other MIB tables, including the monitor table, contain the index value that maps to the entry in the name table.

To assist you in creating the index for the monitor table entries, note that the index value used in the slapm2PolicyRuleStatsTable entries consist of the last value used in the monitor table index, namely the PolicyRuleIndex. Thus, you can walk through the policy statistics table using the following command:

```
osnmp -v walk slapm2PolicyRuleStatsTable```

Then, cut and paste the index value from the PolicyRuleStatsTable and add an OwnerIndex of your choosing at the beginning of the index.

For the above example, the complete index using an OwnerIndex of u1 is:

```
2.117.31.3
|       +--- name table index value (PolicyRuleIndex)
|         +--- length + "u1" (OwnerIndex)```

Monitor table examples

If you are going to change any of the monitor table object values for an existing table entry or row, you must take the row out of service to make the changes. To do this, set the value of
slapm2PRMonRowStatus to 2. After your changes are made, set the row status to a value of 1 to put it back in service.

The following examples show how to create monitor table entries to monitor.

- This example assumes SNMP version 1 security and no SNMPD.CONF file.

1. Enable traps. The snmptrap.dest file should contain the IP address and protocol of an entity to receive traps:

   ```
   /etc/snmptrap.dest   contains: 9.67.191.5       UDP
   /etc/pw.src          contains: public 0.0.0.0    0.0.0.0
   ```

   In this example, use the osnmp command running in the background to receive traps:

   ```
   osnmp trap > /tmp/trap.output &
   ```

2. Change status to notInService:

   ```
   osnmp set slapm2PRMonRowStatus.index 2
   ```

   ```
   osnmp set slapm2PRMonTrapEnable.index 1
   ```

4. If wanted, change default thresholds:

   - TCP round trip, where \( l \) is the lower boundary and \( h \) is the upper boundary:

     ```
     osnmp set slapm2PRMonTcpRttDelayLow.index l
     osnmp set slapm2PRMonTcpRttDelayHigh.index h
     ```

   - TCP retransmit ratio, where \( l \) is the lower boundary and \( h \) is the upper boundary:

     ```
     osnmp set slapm2PRMonTcpReXmitDelayLow.index l
     osnmp set slapm2PRMonTcpReXmitDelayHigh.index h
     ```

   - Accept Queue delay ratio, where \( l \) is the lower boundary and \( h \) is the upper boundary:

     ```
     osnmp set slapm2PRMonAcceptQDelayLow.index l
     osnmp set slapm2PRMonAcceptQDelayHigh.index h
     ```

5. Make row active:

   ```
   osnmp set slapm2PRMonRowStatus.index 1
   ```

- Evaluate the following fields to determine why the slapm2PolicyRuleMonNotOkay trap was generated:

  - If the maxTcpRttDelayExceeded bit in the previous slapm2PRMonStatus is off, indicating below the high threshold, and the bit in the current slapm2PRMonStatus is on, indicating above the high threshold, this indicates that at the end of this monitor interval this is a rising quantity and the threshold has exceeded its high threshold. Evaluate the slapm2PRMonTcpRTTCurrentDelay to determine the average round-trip time over the most recent interval for all outgoing TCP packets affected by this policy rule.

  - If the maxTcpReXmitRatioExceeded bit in the previous slapm2PRMonStatus is off, indicating below the high threshold, and the bit in the current slapm2PRMonStatus is on, indicating above the high threshold, this indicates that at the end of this monitor interval this is a rising quantity and the threshold has exceeded its high threshold. Evaluate the slapm2PRMonTcpCurrentTcpReXmit to determine the TCP retransmit ratio over the most recent interval for all outgoing TCP packets affected by this policy rule.

  - If the maxAcceptQueueDelayExceeded bit in the previous slapm2PRMonStatus is off, indicating below the high threshold, and the bit in the current slapm2PRMonStatus is on, indicating above the high threshold, this indicates that at the end of this monitor interval this is a rising quantity and the threshold has exceeded its high threshold. Evaluate the slapm2PRMonAcceptQCurrentDelay to
determine the smoothed average accept queue delay over the most recent interval for all flows affected by this policy rule.

- Evaluate the following fields to determine why the slapm2PolicyRuleMonOkay trap was generated:
  - If the maxTcpRttDelayExceeded bit in the previous slapm2PRMonStatus is on, indicating above the low threshold, and the bit in the current slapm2PRMonStatus is off, indicating below the low threshold, this indicates that at the end of this monitor interval this is a falling quantity and the threshold has fallen below its low threshold. Evaluate the slapm2PRMonTcpRTTCurrentDelay to determine the average round-trip time over the most recent interval for all outgoing TCP packets affected by this policy rule.
  - If the maxTcpReXmitRatioExceeded bit in the previous slapm2PRMonStatus is on, indicating above the low threshold, and the bit in the current slapm2PRMonStatus is off, indicating below the low threshold, this indicates that at the end of this monitor interval this is a falling quantity and the threshold has fallen below its low threshold. Evaluate the slapm2PRMonTcpCurrentTcpReXmit to determine the TCP retransmit ratio over the most recent interval for all outgoing TCP packets affected by this policy rule.
  - If the maxAcceptQueueDelayExceeded bit in the previous slapm2PRMonStatus is on, indicating above the low threshold, and the bit in the current slapm2PRMonStatus is off, indicating below the low threshold, this indicates that at the end of this monitor interval this is a falling quantity and the threshold has fallen below its low threshold. Evaluate the slapm2PRMonAcceptQCurrentDelay to determine the smoothed average accept queue delay over the most recent interval for all flows affected by this policy rule.
Chapter 16. Intrusion detection services

It is becoming increasingly important to not just protect systems from attacks but to detect patterns of usage that might indicate impending attacks. Many attacks follow a sequence of information gathering, unauthorized access to resources (information, applications, storage), and denial of service. It can be difficult, or at times, impossible to determine the originator of denial of service attacks. Correlating information gathering activities with access violation might help identify an intruder before they succeed.

Intrusion detection services (IDS) provides the following support:

- Scan detection and reporting
- Attack detection, reporting, and prevention
- Traffic regulation for TCP connections and UDP receive queues

You can use IDS policies to specify event conditions and the actions to take for particular events. All IDS policies support logging events to a specified message priority level in syslogd, on the system console, or both. Most IDS policies support the following functions:

- Discarding packets when a specified limit is reached
- Writing statistical records to the INFO message level of syslogd at a specified time interval, and the option to write these records only when exceptional events have occurred
- Tracing all or part of the triggering packet to an IDS-specific CTRACE facility, SYSTCPIS

IDS assigns a correlator value to each event. All messages written to the system console and syslogd use this correlator, and records written to the IDS trace use this correlator. A single detected event can involve multiple packets; the correlator value identifies which messages and packets are related to each other. Each IDS policy has additional attributes that you can specify, either in conditions or in the action.

Scan policies

Scans are recognized when a single source IP address makes multiple attempts to gather information within a defined period of time. Although a scan is not harmful, many serious attacks, especially access violation attacks, are preceded by scans to gather information. Scans must use reliable source IP addresses and can be interesting events to monitor.

IDS support defines a scanner as a source host that accesses multiple unique resources (ports or interfaces) over a specified period of time. You can specify the number of unique resources (Threshold) and the time period (Interval) by policy. Two categories of scans are supported:

- Fast scan
  Many resources are rapidly accessed in a short time period (usually less than 5 minutes and program driven)
- Slow scan
  Different resources are intermittently accessed over a longer period of time (many hours). This could be a scanner trying to avoid detection.

The following scenarios are some examples of a scanner:

- Source host A has a program that loops through all low ports and tries to connect to each port on target host X (fast scan). Each port is considered a unique resource.
- Source host B manually sends a ping command to each interface on target host X, and then tries to access well-known ports on target host X (most likely a slow scan). Each interface accessed by a ping command is considered a unique resource, and each port accessed is considered a unique resource.

The following scenario is not considered to be an example of a scanner:
• Source host C starts 20 connections to port 23. Because these connections are to the same port, only one unique resource is accessed, and host C is not considered a scanner.

Scans like the one in the following scenario might not be detected by IDS:

• Source host E issues a ping command to IP addresses 9.1.1.1 through 9.255.255.255. Because host X collects data only for the ping commands that are directed to interfaces of host X, this event is not detected by host X as a scan. Network IDS might detect this as wide scan.

Scan policy provides the ability to specify the following conditions and actions:

• Fast scan time interval
• Slow scan time interval
• Fast scan threshold
• Slow scan threshold
• Exclude well-known legitimate scanners by using an exclusion list
• Specify a sensitivity level by port or port range (to reduce performance impacts)
• Provide notification of a detected scan by issuing a console message or a syslogd message
• Trace potential scan packets

The individual packets used in a scan are categorized as normal, possibly suspicious, or very suspicious. To control the performance impact and analysis load of scan monitoring, set the sensitivity level for potential scan events to high, medium, or low.

Table 44 on page 824 shows how the policy-specified sensitivity affects the counting of scan events. The event suspicion level is determined by the stack.

<table>
<thead>
<tr>
<th>Sensitivity (from policy)</th>
<th>Normal event</th>
<th>Possibly suspicious event</th>
<th>Very suspicious event</th>
</tr>
</thead>
<tbody>
<tr>
<td>Low</td>
<td></td>
<td>counted</td>
<td>counted</td>
</tr>
<tr>
<td>Medium</td>
<td></td>
<td>counted</td>
<td>counted</td>
</tr>
<tr>
<td>High</td>
<td>counted</td>
<td>counted</td>
<td>counted</td>
</tr>
</tbody>
</table>

To help reduce or eliminate false positive results, IDS allows policy-specified source IP addresses, subnet masks, and optionally, source port numbers, to be excluded from scan detection. For UDP and TCP port scans, you can limit scan detection to specific destination port ranges. You can specify the sensitivity level (high, medium, or low) for these port ranges.

Another way that IDS reduces false positive results is by counting only unique events from a specific source IP address within a scan interval. An event is considered unique if the IP protocol, destination IP address, and destination port (UDP or TCP) or type (ICMP) have not been encountered before during this scan interval.

IDS scan policy supports a fast scan interval and threshold, and a slow scan interval and threshold:

• Fast scan

A fast scan is recognized if the number of unique events within the fast scan interval reaches the fast scan threshold.

• Slow scan

A slow scan is recognized if the number of unique events within the slow scan interval reaches the slow scan threshold.

IDS counts scan events using an internal interval that is no greater than half of the fast scan interval. During an internal interval, after the number of unique events reaches the slow scan threshold, additional
events are not counted. These additional events are traced if requested by policy using the trace data parameter in the action.

**Restriction:** When system resources are constrained, IDS might temporarily suspend scan detection.

Scan events are categorized by the following scan types:

- ICMP scans
- ICMPv6 scans
- UDP port scans
- TCP port scans

Any countable scan event is counted against the origin source IP address, and the total number of countable events from all categories is compared to the policy thresholds. When an origin source IP address has reached the fast or slow threshold defined by policy, the following actions are taken if you requested them using the notification options in the action:

- A notification is sent to the traffic regulation management daemon (TRMD) for logging to syslogd
- A console message is issued
- The packet is logged to the IDS packet trace

When IDS detects a scan for a particular source IP address, no further scan events are reported for that source IP address during the specified interval. The intervals and thresholds for fast and slow scans are global; one set of values applies to all event categories.

**ICMP scans**

Internet Control Message Protocol (ICMP) requests (Echo, Information, Timestamp, and Subnet Mask) are used to map network topology. Receipt of an ICMP request is classified as a normal, possibly suspicious, or highly suspicious event. Any request sent to a multicast or broadcast address is treated as a very suspicious event. Echo requests (ping) and Timestamp requests are common and are treated as normal events when they do not include the IP Options for Record Packet Route or Record Timestamp. Events are classified by the first matching entry in Table 45 on page 825:

<table>
<thead>
<tr>
<th>Event</th>
<th>Destination address</th>
<th>Event classification</th>
</tr>
</thead>
<tbody>
<tr>
<td>Receive any ICMP request (Echo, Information, Timestamp, or Subnet Mask)</td>
<td>Multicast or broadcast</td>
<td>Very suspicious</td>
</tr>
<tr>
<td>Receive any ICMP request that is denied by Quality of Service (QoS) policy</td>
<td>Unicast</td>
<td>Normal</td>
</tr>
<tr>
<td>Receive Information Request or Subnet Mask</td>
<td>Unicast</td>
<td>Possibly suspicious</td>
</tr>
<tr>
<td>Receive Echo Request with IP Option Record Route or Record Timestamp</td>
<td>Unicast</td>
<td>Possibly suspicious</td>
</tr>
<tr>
<td>Receive Echo Request or receive Timestamp Request</td>
<td>Unicast</td>
<td>Normal</td>
</tr>
</tbody>
</table>

**ICMPv6 scans**

ICMPv6 provides ICMP function for IPv6. Table 46 on page 826 shows the ICMPv6 events that are considered for scan detection and the suspicion level associated with each event. Events are classified by the first matching entry in the table.
Table 46. Classification of ICMPv6 events

<table>
<thead>
<tr>
<th>Event</th>
<th>Destination address</th>
<th>Event classification</th>
</tr>
</thead>
<tbody>
<tr>
<td>Receive Echo Request</td>
<td>Multicast</td>
<td>Very suspicious</td>
</tr>
<tr>
<td>Receive Echo Request that is denied by Quality of Service (QoS) policy</td>
<td>Unicast</td>
<td>Normal</td>
</tr>
<tr>
<td>Receive Echo Request with Routing Header</td>
<td>Unicast</td>
<td>Possibly suspicious</td>
</tr>
<tr>
<td>Receive Echo Request without Routing Header</td>
<td>Unicast</td>
<td>Normal</td>
</tr>
</tbody>
</table>

**UDP port scans**

Because UDP is stateless, the stack cannot differentiate between a client port and a server port. A scanner that is sending messages to many ephemeral ports looks similar to a DNS server that is sending replies to many clients on ephemeral ports. You can specify the RESERVED keyword on the PORT or PORTRANGE statement in the TCP/IP profile to prohibit the use of a UDP port. Any datagram that is received for a prohibited port is treated as a very suspicious event. Any datagram that is received for a port that is not prohibited but is unbound is treated as a possibly suspicious event, and any datagram received for a bound port is treated as a normal event. You can also limit event generation to specific port ranges and destination addresses. UDP port scans apply to IPv4 and IPv6 packets. Events are classified by the first matching entry in Table 47 on page 826:

Table 47. UDP port event classification

<table>
<thead>
<tr>
<th>Socket state</th>
<th>Event</th>
<th>Event classification</th>
</tr>
</thead>
<tbody>
<tr>
<td>Any state</td>
<td>Receive any packet that is denied by IP security filtering</td>
<td>Possibly suspicious</td>
</tr>
<tr>
<td>Use prohibited by RESERVED keyword</td>
<td>Receive any packet</td>
<td>Very suspicious</td>
</tr>
<tr>
<td>Unbound, use not prohibited</td>
<td>Receive any packet</td>
<td>Possibly suspicious; application could be temporarily down</td>
</tr>
<tr>
<td>Bound</td>
<td>Receive any packet</td>
<td>Normal</td>
</tr>
</tbody>
</table>

**TCP port scans**

Because TCP is a stateful protocol, many different events might be classified as normal, possibly suspicious, or very suspicious. The identified conditions are listed in Table 48 on page 826. You can use the RESERVED keyword on the PORT or PORTRANGE statement in the TCP/IP profile to prohibit the use of a TCP port. You can also limit event generation to specific port ranges and destination IP addresses. TCP port scans apply to IPv4 and IPv6. Events are classified by the first matching entry in Table 48 on page 826:

Table 48. TCP port event classification

<table>
<thead>
<tr>
<th>Socket state</th>
<th>Event</th>
<th>Event classification</th>
</tr>
</thead>
<tbody>
<tr>
<td>Any state</td>
<td>Receive unexpected flags (for example, SYN+FIN)</td>
<td>Very suspicious</td>
</tr>
</tbody>
</table>
Table 48. TCP port event classification (continued)

<table>
<thead>
<tr>
<th>Socket state</th>
<th>Event</th>
<th>Event classification</th>
</tr>
</thead>
<tbody>
<tr>
<td>Any state</td>
<td>Receive standalone SYN that is denied by IP security filtering</td>
<td>Possibly suspicious</td>
</tr>
<tr>
<td>Use prohibited by RESERVED keyword</td>
<td>Receive standalone SYN</td>
<td>Very suspicious</td>
</tr>
<tr>
<td>Unbound, use not prohibited</td>
<td>Receive standalone SYN</td>
<td>Possibly suspicious; application could be temporarily down</td>
</tr>
<tr>
<td>Listen</td>
<td>Receive standalone SYN that is denied by Quality of Service (QoS) policy</td>
<td>Normal</td>
</tr>
<tr>
<td>Listen</td>
<td>Receive standalone SYN</td>
<td>No event (classification deferred)</td>
</tr>
<tr>
<td>Half open connection</td>
<td>Receive ACK</td>
<td>Normal; connection handshake completed</td>
</tr>
<tr>
<td>Half open connection</td>
<td>Receive duplicate SYN</td>
<td>Normal; perhaps duplicate packet</td>
</tr>
<tr>
<td>Half open connection</td>
<td>Receive RST</td>
<td>Possibly suspicious; peer covering tracks</td>
</tr>
<tr>
<td>Half open connection</td>
<td>Final time out</td>
<td>Very suspicious; peer abandoned handshake</td>
</tr>
<tr>
<td>Any connected state</td>
<td>Seq# out of window</td>
<td>Normal; perhaps duplicate packet</td>
</tr>
<tr>
<td>Any connected state</td>
<td>Receive standalone SYN</td>
<td>Normal; perhaps peer reboot</td>
</tr>
<tr>
<td>Any connected state</td>
<td>Final timeout</td>
<td>Possibly suspicious; peer abandoned connection</td>
</tr>
</tbody>
</table>

**Attack policies**

An attack can be a single packet designed to cause a system to fail or hang. An attack can also consist of multiple packets designed to consume a limited resource, which causes a network, system, or application to be unavailable to its intended users (denial of service). You can use intrusion detection services (IDS) attack policy to activate attack detection for one or more categories of attacks independently of each other. In general, the types of actions that you can specify for an attack policy are event logging, statistics gathering, packet tracing, and discarding of the attack packets. Most attack checking is performed for inbound packets to a stack.

IDS includes the following categories of attacks:

- **Malformed packet events**
  
  Many attacks are designed to cause the protocol stack of a system to fail by providing incorrect or partial header information. These packets are always discarded when they are received, regardless of IDS policy. The source IP address is rarely reliable for these attacks. This type of attack applies to both IPv4 and IPv6 packets.
  
  You can use IDS policy to provide notification of malformed packet attacks.

- **Inbound fragment events**
Many attacks are the result of fragment overlays in the IP or transport header. You can use this support to detect fragmentation overlays that change the data in a packet, including changes to the length of the packet. This type of attack applies to both IPv4 and IPv6 packets.

You can use IDS policy to provide notification of suspicious fragments, and optionally to discard them.

- **IP protocol restrictions**

  Although there are 256 possible values that can be specified in the protocol field of the IP header, only a handful are commonly used. You can protect your system against future attacks by prohibiting those values that you are not actively and intentionally using.

  **Restriction:** This attack type applies to IPv4 packets only. The IPv6 next header restrictions attack type provides analogous function for IPv6 packets.

  You can use IDS policy to provide notification of a packet with a restricted IP protocol value, as well as to discard the packet.

- **IPv6 next header restrictions**

  The IPv6 header and any subsequent extension headers include a next header field. The value in the next header field identifies the next header in the packet, either an upper layer protocol header (such as a TCP or UDP header) or an extension header (such as a fragmentation or routing header). Although there are 256 possible values that can be specified as a next header value, only a small number are commonly used. You can protect your system by prohibiting next header values in inbound packets that you are not actively and intentionally using.

  **Restriction:** This attack type applies to IPv6 packets only. The IP protocol restrictions and IP option restrictions attack types provide analogous function for IPv4 packets.

  You can use IDS policy to provide notification of an inbound packet with a restricted next header value, as well as to discard the packet.

- **IP option restrictions**

  As with IP protocols, there are 256 possible values that can be specified as IP options in received packets, with only a small number currently in common use. You can prevent misuse of values that you are not intentionally using. A check for restricted IP options is performed on all inbound packets, including those that are forwarded to another system.

  **Restriction:** This attack type applies to IPv4 packets only. The IPv6 destination option restrictions, IPv6 hop-by-hop option restrictions, and IPv6 next header restrictions attack types provide analogous function for IPv6 packets.

  You can use IDS policy to provide notification of a packet with a restricted IP option, as well as to discard the packet.

- **IPv6 destination option restrictions**

  Although there are 256 possible values that can be specified as IPv6 destination options in received packets, only a small number of values are currently defined. You can prevent misuse of values that you are not intentionally using.

  **Restriction:** This attack type applies to IPv6 packets only. The IP option restrictions attack type provides analogous function for IPv4 packets.

  You can use IDS policy to provide notification of a packet with a restricted value for an IPv6 destination option, as well as to discard the packet.

- **IPv6 hop-by-hop option restrictions**

  Although there are 256 possible values that can be specified as IPv6 hop-by-hop options in received packets, only a small number of values are currently defined. You can prevent misuse of values that you are not intentionally using. A check for restricted IPv6 hop-by-hop options is performed on all inbound packets, including those that are forwarded to another system.

  **Restriction:** This attack type applies to IPv6 packets only. The IP option restrictions attack type provides analogous function for IPv4 packets.
You can use IDS policy to provide notification of a packet with a restricted value for an IPv6 hop-by-hop option, as well as to discard the packet.

- **UDP perpetual echo**

Some UDP applications unconditionally respond to every datagram that is received. In some cases, such as Echo, CharGen or TimeOfDay, this is a useful network management or network diagnostic tool. In other cases, an application might send error messages in response to incorrectly formed requests. If a datagram is inserted into the network with one of these applications as the destination and another one of these applications spoofed as the source, the two applications will respond to each other continually. Each inserted datagram results in another perpetual echo conversation between them. You can use IDS policy to define the application ports that exhibit this behavior. This type of attack applies to both IPv4 and IPv6 packets.

You can use IDS policy to provide notification of a perpetual echo packet, as well as to discard the packet.

- **ICMP redirect events**

ICMP redirect packets and ICMPv6 redirect packets can be used to modify your routing tables. You can use IDS policy to provide notification of attempts to modify your routing tables in this manner. You can also use IDS policy to ignore ICMP redirect packets and ICMPv6 redirect packets.

**Tip:** ICMP redirect packets are ignored if IPCONFIG IGNOREREDIRECT is specified in the TCP/IP profile, you are using OMPROUTE and you have IPv4 interfaces configured to OMPROUTE, or IDS policy is active for ICMP redirect attacks and the associated policy action requests that the packet be discarded. ICMPv6 redirect packets are ignored if IPCONFIG6 IGNOREREDIRECT is specified in the TCP/IP profile, you are using OMPROUTE and you have IPv6 interfaces configured to OMPROUTE, or IDS policy is active for ICMP redirect attacks and the associated policy action requests that the packet be discarded.

- **Outbound raw restrictions**

Most network attacks require the ability to create packets that would not typically be built by an appropriate protocol stack implementation. You can use IDS policy to detect and prevent many of these attempts so that your system is not used as the source of attacks on other systems. As a part of this checking, you can restrict the IP protocols that are allowed in an outbound raw packet.

**Guideline:** You should restrict the TCP protocol (6) on the outbound raw rule.

**Restriction:** This attack type applies to IPv4 packets only. The IPv6 outbound raw restrictions attack type provides analogous function for IPv6 packets.

You can use IDS policy to provide notification of an outbound raw packet that is considered an attack, as well as to discard the packet.

- **IPv6 outbound raw restrictions**

Most network attacks require the ability to create packets that would not normally be built by an appropriate protocol stack implementation. You can use IDS policy to detect and prevent many of these attempts so that your system is not used as the source of attacks on other systems. As a part of this checking, you can restrict the protocols that are allowed in an outbound raw packet for IPv6 traffic.

**Guideline:** You do not need to restrict the TCP protocol (6) for IPv6 because a TCP packet cannot be generated using AF_INET6 raw sockets.

**Restrictions:**

- You cannot restrict which IPv6 extension headers are allowed in an outbound raw packet with this attack type. The restricted protocol list applies to only the upper layer protocol for which the raw socket is opened. If any of the following extension header values are included in the restricted protocol list, it will have no effect:
  - HOPOPT (0)
  - IPv6 (41)
  - IPv6-Route (43)
  - IPv6-Frag (44)
This attack type applies to IPv6 packets only. The outbound raw restrictions attack type provides analogous function for IPv4 packets.

You can use IDS policy to provide notification of an outbound IPv6 raw packet that is considered an attack, as well as to discard the packet.

- **Flood events**

  Two types of floods are currently detected:

  - **TCP SYN floods**
    
    A popular denial of service attack is to flood a public server with connection requests from incorrect or nonexistent source IP addresses. The intent is to use up the available slots for connection requests and thereby deny legitimate access from completing. z/OS CS provides protection from this attack regardless of IDS policy.

  - **Interface floods**

    If a large number of discards are occurring in proportion to the number of inbound packets, a malicious user might be attempting a denial of service attack. If this percentage of discards for an interface exceeds a specified percentage, this is considered an interface flood. The default percentage of discards used is 10%. You can override this default by specifying the interface flood percentage parameter.

    To prevent the false detection of an interface flood condition when there is a low volume of inbound traffic on an interface, a minimum number of discards must occur in a one minute period to qualify as a flood. The default minimum is 1000 discards per minute. You can override this default by specifying the interface flood minimum discard parameter.

    When an interface flood condition is reported for an interface, the discard rate for the interface is evaluated for each subsequent 1-minute interval. An interface flood condition end is reported when the number of discards for the 1-minute interval falls below the interface flood minimum discard parameter value or the discard percentage falls below 50% of the interface flood percentage parameter value.

    If the interface flood continues for more than 5 minutes and logging was requested by policy, an interface flood continues record is logged at 5 minute intervals while the interface flood conditions exist. This log data contains additional information about the discarded packets for the interface.

    Because it can be difficult to distinguish between a malicious user trying to flood a system, unusual spikes in traffic, and problems that can be caused by setup problems, it is possible for an interface flood condition to be reported when the source of the problem is not actually a flood. For example, if enough storage is not configured to handle the inbound traffic, a large percentage of the inbound packets might be discarded and cause the interface flood percentage to be exceeded.

    This type of attack applies to both IPv4 and IPv6.

    You can use IDS policy to provide notification of an attack so that you can address the situation with your network administrators and service providers in a timely manner. Notification of a flood can include flood start and flood end event messages and tracing of the first 100 packets discarded due to the flood.

- **Enterprise Extender (EE) malformed packet events**

  Malformed packets for EE can be designed to disrupt the TCP/IP and SNA protocol stacks. These packets might have incorrect information in the IP and UDP headers, and the received packet might be too short or too long depending on the Logical Data Link Control (LDLC) command present. Any packet received that is not a valid EE command is flagged as malformed.

  You can use the IDS policy option to discard malformed packets or to forward them to VTAM for further processing. You can use IDS policy to provide notification of the EE malformed packets. You can code an
exclusion list in the policy to exclude packets from certain IP addresses from the malformed packet checks.

**Guideline:** If the existing behavior of a remote peer is flagged as an attack and you determine that it is not an actual problem, you can choose to exclude the peer from malformed packet checking by adding the peer to the exclusion list. You can configure an exclusion by specifying the remote IP address, and optionally the remote ports.

This type of attack applies to both IPv4 and IPv6 packets.

- **EE LDLC check events**

  EE architecture defines five ports that map to SNA data priorities. The lowest port, usually 12000, is used for signaling data. If signaling data is received on any of the other ports, it is suspicious. If the EE LDLC check attack type is enabled, receiving signaling data on any of the other ports is detected as an attack. This type of attack can be a denial of service (DoS) attack designed to keep resources busy, so that SNA LUs are not able to start sessions with applications on this host.

  IDS policy gives you the option of discarding these packets or forwarding them to VTAM for further processing. You can configure the policy to provide notification of the LDLC events. You can code an exclusion list in the policy to exclude packets from certain IP addresses from the LDLC checks.

  **Guideline:** If the existing behavior of a remote peer is flagged as an attack and you determine that it is not an actual problem, you can choose to exclude the peer from LDLC event checking by adding the peer to the exclusion list. You can configure an exclusion by specifying the remote IP address, and optionally, the remote ports.

  This type of attack applies to both IPv4 and IPv6 packets.

- **EE port check events**

  You can use IDS policy to check the source and destination ports in the UDP header of received EE packets. The port values are expected to be the same; for example, both source and destination port are 12000 in a received packet. If the port values are not the same, this packet is considered an attack packet.

  IDS policy gives you the option of discarding these packets or forwarding them to VTAM for further processing. You can configure the policy to provide notification of the port detection events. You can code an exclusion list in the policy to exclude packets from certain IP addresses from the port checks. For example, some products send the null XID using an ephemeral source port value, but expect the reply to be sent to the EE signaling port.

  **Guideline:** If the existing behavior of a remote peer is flagged as an attack and you determine that it is not an actual problem, you can choose to exclude the peer from port checking by adding the peer to the exclusion list. You can configure an exclusion by specifying the remote IP address, and optionally, the remote ports.

  This type of attack applies to both IPv4 and IPv6 packets.

- **EE XID flood event**

  A flood of XIDs can consume all available EE lines, causing additional EE connection requests to fail. You can enable the EE XID flood attack type to receive notification when an XID flood is occurring for a specific VIPA.

  An XID flood is detected when a large number of XID exchanges time out. No discard action exists for this attack type. You can code an exclusion list in the policy to exclude XID exchanges that time out from being counted toward the XID flood if the peer's IP address is in the exclusion list.

  **Guideline:** If the existing behavior of a remote peer is flagged as an attack and you determine that it is not an actual problem, you can choose to exclude the peer from XID flood checking by adding the peer to the exclusion list. You can configure an exclusion by specifying the remote IP address, and optionally, the remote ports.

  This type of attack applies to both IPv4 and IPv6 packets.

- **Data hiding events**
Certain fields within a packet can be used to hide data. This support enables you to detect inbound IP packets that might contain hidden data. The following checks for hidden data can be enabled:

- Check IP option pad fields for hidden data:
  - For IPv4 packets, the options field is in the IP header and can contain padding for alignment purposes.
  - For IPv6 packets, a hop-by-hop options extension header or a destination options extension header can include one or more PadN options for alignment purposes.

- Check embedded packets within ICMP and ICMPv6 error messages for hidden data.

This type of attack applies to both IPv4 and IPv6 packets.

You can use IDS policy to provide notification of a suspicious packet that might contain hidden data, as well as to discard the packet.

TCP queue size events

You can use IDS policy to detect when the send, receive, or out-of-order queue for a TCP connection becomes constrained. A queue can be constrained due to the amount of data on the queue or due to the age of the data on the queue. When a designated amount of data that is configured in policy remains on the queue for at least 30 seconds, the queue becomes constrained. When any data remains on the queue for at least 60 seconds, the queue becomes constrained. Optionally, you can reset the TCP connection when a constraint is detected. If you do not reset the TCP connection, IDS continues to monitor the queue and detect when it becomes unconstrained. This type of attack applies to both IPv4 and IPv6 connections.

IDS policy for TCP queue size events specifies one of four abstract queue sizes:

- VERY_SHORT
- SHORT
- LONG
- VERY_LONG

The actual queue sizes associated with these abstract values are internal values that represent a percentage of the total size of each queue, and are subject to change. Most TCP applications have timeout values that are based on human perceptions of responsiveness. These values tend to stay constant, while system processing speeds and network delivery speeds continue to advance rapidly, which might require that the queue sizes associated with these abstract values be changed over time.

A TCP connection might have data queued on the send queue for a long period of time for a legitimate reason. For example, a TCP connection that is associated with a printer that has run out of paper can remain in a persist state while waiting for paper to be loaded. To exclude a device, such as a printer, from TCP send queue size checking, you can configure an exclusion specifying the IP address, and optionally the port, of the device.

You can use IDS policy to provide notification of a constrained send, receive, or out-of-order queue, as well as to reset the connection.

Global TCP stall events

There are attacks designed to consume system resources by creating many TCP connections and causing them to stall, making them unable to send data. This support detects a global TCP stall condition for a TCP/IP stack when at least 50% of the active TCP connections are stalled and at least 1000 TCP connections are active. Optionally, you can reset the stalled connections. This type of attack applies to both IPv4 and IPv6 connections.

For each attack category (for example, restricted IP protocol) the single highest priority rule is mapped at policy change.

One or more notification options can be specified in the action to provide the wanted documentation of detected attacks.
For IDS attack policy, the notification options enable attack events to be logged to syslogd and to the system console. The console messages provide a subset of the information provided in the syslogd messages.

For all attack categories except flood, EE XID flood, TCP queue size, and global TCP stall, a single packet triggers an event. To prevent message flooding to the system console, you should use the maximum event message parameter to specify the maximum number of console messages to be logged per attack category within a 5-minute interval. To prevent message flooding to syslogd, a maximum of 100 event messages per attack category are logged to syslogd within a 5-minute interval. Specify the syslogd detail parameter with the global TCP stall attack type to request that a syslogd message be generated for each stalled connection when a global TCP stall is detected.

For IDS attack policy, the statistics action provides a count of the number of attack events detected during the statistics interval. The count of attacks is kept separately for each category of attack (for example, malformed packet events) and a separate statistical record is generated for each. If you want to receive statistics for attacks, you should specify exception statistics. With exception statistics, a statistical record is generated for the category of attack only if the count of attacks is nonzero. If you request normal statistics, a record is generated for every statistics interval regardless of whether an attack has been detected during that interval.

If you want to provide overrides to the interface flood parameters (interface flood minimum percentage parameter and interface flood minimum discard parameter), you should not use exception statistics. In this case, use normal statistics for a period for the flood attack category to collect data to help determine the appropriate policy parameter values. After you determine the appropriate values, specify exception statistics.

For IDS attack policy, the trace data and trace record size parameters indicate whether packets associated with attack events are to be traced. For all attack categories except flood, EE XID flood, TCP queue size, and global TCP stall, a single packet triggers an event and the packet is traced. To prevent trace flooding, a maximum of 100 attack packets per attack category are traced within a 5-minute interval.

- For the flood category, the first 100 packets discarded during a SYN flood are traced. In the case of an interface flood, the flood is detected on an interface basis and the trace limit is applied on an interface basis.
- For EE XID flood, TCP queue size, and global TCP stall, no data is traced.

For all attack categories except EE XID flood, TCP queue size, and global TCP stall, you can specify that packets associated with attack events should be discarded. However, malformed and flood packets are always discarded regardless of this setting.

For the TCP queue size attack category, you can specify that connections associated with attack events should be reset.

For the global TCP stall attack category, you can specify that stalled connections should be reset when a global TCP stall condition is detected.

The EE XID flood attack category monitors the number of XID exchange timeouts. There is no associated packet to discard or connection to reset.

An action can be unique to a specific category of attack (for example, malformed) or shared by one or more categories of attacks. If an action is shared, statistical data is still kept separately for each type of attack. Also, the maximum console message limit is enforced individually for each category of attack.

**Traffic regulation policies**

IDS traffic regulation (TR) policies are used to limit memory resource consumption and queue delay time during peak loads.
**Traffic regulation policies for TCP ports**

IDS traffic regulation (TR) policies for TCP ports limit the total number of connections an application has active at one time. This can be used to limit the number of address spaces created by forking applications such as FTPD and telnetd. A *fair share* algorithm is also provided based on the percentage of remaining available connections already held by a source IP address.

The percentage is applied against the number of available connections for the port. Therefore, as fewer connections become available, each host is allowed fewer new connections. The percentage is applied against the number of available connections, rather than the total number of connections allowed, in order to allow access to a larger number of different hosts when resources are low.

When a host requests a connection, the number of connections it currently holds for the port is compared to the percentage applied to the connections currently available for the port. If the number currently held is less than the percentage of currently available connections, the host is allowed to open an additional connection. If equal or greater, the host is not allowed to open further connections until more connections are freed up. All connection requesters for the port are regulated by this mechanism. If a host does not currently have any connections open on the port and unused connections are available, a host will always be allowed at least 1 connection. Multi-user source IP addresses can be allowed a larger number of connections by specifying a QoS policy with a higher number of connections (MaxConnections) than allowed by the TR policy. TR will honor the QoS differentiated services policy if the port is not in a *constrained state*. A QoS exception is made only when QoS differentiated service policy is applied for the specific source server port and specific outbound client destination IP address; if either of these attributes specify a range or are null, the QoS exception will not be made.

TR TCP generates a Constrained Event when a port reaches about 90% of its Connection Limit. An Unconstrained Event is generated when the port falls below about 88% of its limit. An IDS correlator is assigned for the duration of each constrained state. If tracing is requested in the policy, the first 100 packets that exceed the limit in each constrained state are traced along with the correlator. TR TCP also generates events for each connection allowed because of a QoS override policy and for each connection denied for exceeding either the application's connection limit or the percent available limit.

To prevent possible flooding of syslog, TR TCP limits the number of connection refused, would have been refused, or QOS exception log records written in a five minute interval. For a listening port, a maximum of 100 of these log records are written within a five minute interval. Globally, TR TCP writes a maximum of 1000 of these log records within a five minute interval. If a log record was not written due to these limits, the count of refused or would have been refused connection log records that were not logged is recorded in the EZZ8660I TRMD TCP connection log records suppressed log message after the five minute interval ends. Similarly, the count of QOS exception records that were not written is recorded in the EZZ8661I TRMD TCP QOS exception log records suppressed log message.

TCP traffic regulation policy applies to IPv4 and IPv6.

**Guideline:** TR TCP is intended for use with long-running servers, which typically use well-known ports or ports that are reserved for TCP applications. You should not use TR TCP to monitor transitory listeners; doing so can result in high storage usage. An example of a transitory listener is an FTP data connection that lasts only as long as it takes to move one file and typically uses ports above 1023.

**Traffic regulation policies for UDP ports**

Previously, control over UDP based applications consisted of application priority management and the TCP/IP profile parameter UDPQueueLimit ON | OFF. Inbound datagrams for bound UDP ports are accepted and queued until the queue limit is reached or buffer memory is exhausted. If UDPQueueLimit is set to OFF, any single bound port under a flood attack or with a stalled application could consume all available buffer storage. It is recommended that UDPQueueLimit always be set to ON. This limits the amount of storage that can be consumed by inbound datagrams for any single bound port. Sockets that use the Pascal API, have a limit of 160 KB in any number of datagrams. Sockets that use other APIs, have a limit of 2000 datagrams or 2880 KB.

IDS traffic regulation (TR) policies for UDP ports specify one of four abstract queue sizes for specified bound IP addresses and ports. The four abstract sizes are VERY_SHORT, SHORT, LONG and VERY_LONG. The actual queue sizes associated with these abstract values are internal values that are subject to

---

834 z/OS Communications Server: IP Configuration Guide
change. Most UDP applications have timeout values based on human perceptions of responsiveness. These values tend to stay constant while system processing speeds and network delivery speeds continue to advance rapidly. This might require the queue sizes associated with these abstract values to change over time. The initial implementation uses the values of 16, 256, 2048 and 8192 for the number of datagrams and an average datagram size of 2 KB to calculate the byte sizes (32 KB, 512 KB, 4 MB, 16 MB). For performance reasons, sockets that use the Pascal API will enforce only the byte limit. Sockets that use other APIs will enforce both limits. Sockets without a policy specified for their port will use the existing UDPQueueLimit mechanism.

For applications that can process datagrams at a rate faster than the average arrival rate, the queue acts as a speed matching buffer that shifts temporary peak workloads into following valleys. The more that the application processing rate exceeds the average arrival rate and the larger the queue, the greater the variation in arrival rates that can be absorbed without losing work. Very fast applications with highly variable (“bursty”) traffic patterns might benefit from LONG or VERY_LONG queue sizes.

For applications that consistently receive datagrams at a higher rate than they are able to process them, the queue limits the effective arrival rate to the processing rate by discarding excess datagrams. In this case the queue size influences only the average wait time of datagrams in the queue and not the percentage of work lost. In fact, if the wait time gets too large, the peer application might have given up or retransmitted the datagram before it is processed. Slow applications with consistently high traffic rates might benefit from SHORT queue sizes.

In general, client side applications will tend to have lower system priority giving them lower datagram processing rates. They also tend to have much lower datagram arrival rates. Giving them SHORT or VERY_SHORT queue sizes might reduce the risk to system buffer storage under random port flood attacks with little impact on percentage of datagrams lost.

TR UDP generates a Constrained Event when a port reaches about 90% of its Queue Limit. An Unconstrained Event is generated when the port falls below about 88% of its limit. An IDS correlator is assigned for the duration of each constrained state. If tracing is requested in the policy, the first 100 packets that exceed the limit in each constrained state are traced along with the correlator.

UDP traffic regulation policy applies to IPv4 and IPv6.

**Options for configuring IDS**

You configure IDS using a set of configuration statements and parameters coded into a flat file, which is parsed by the Policy Agent to establish the IDS policy for each TCP/IP stack. In a complex environment, this file can become large. For this reason, there are two alternatives for creating the Policy Agent files.

**Option 1: Use the IBM Configuration Assistant for z/OS Communications Server**

The IBM Configuration Assistant for z/OS Communications Server, a GUI-based tool, provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the IBM Configuration Assistant for z/OS Communications Server to generate the Policy Agent files.

The IBM Configuration Assistant for z/OS Communications Server is a z/OS Management Facility (z/OSMF) task. z/OSMF provides a web browser interface for a variety of z/OS system management functions. When you invoke the IBM Configuration Assistant for z/OS Communications Server in z/OSMF, the IBM Configuration Assistant for z/OS Communications Server runs natively in the z/OS system and you can access it through a web browser.

Through a series of wizards and online help panels, you can use the IBM Configuration Assistant for z/OS Communications Server to create IDS configuration files for any number of z/OS images with any number of TCP/IP stacks per image. Using the IBM Configuration Assistant for z/OS Communications Server, there are two types of reusable objects:

- Traffic descriptors that define the IP traffic type, such as TCP or UDP.
- Requirement maps that contain attack protection, scan protection, and traffic regulation. For scan protection and traffic regulation, traffic descriptors are used to identify the local applications that are
provided the protection and regulation. A single requirement map should contain a complete set of IDS requirements that will govern the level of IDS for a TCP/IP stack.

For each TCP/IP stack, you select a requirement map that provides IDS for the stack. The IBM Configuration Assistant for z/OS Communications Server comes with a number of IBM-supplied traffic descriptors and a default requirement map that are easily applied, or you can use the IBM-supplied definitions as the basis for your own set of reusable objects.

The IBM Configuration Assistant for z/OS Communications Server can dramatically reduce the amount of time that is required to create IDS policy files, contributing to ease of configuration and maintenance. Because of the inherently complex nature of z/OS security configuration, using the GUI can help you ensure that you have a consistent and easily manageable interface for implementing IDS.

The information in “Defining IDS policies” on page 836 primarily describes option 2, manual configuration. However, if you are using the IBM Configuration Assistant for z/OS Communications Server, reading this information will help you understand security concepts and the relationship between Policy Agent and IDS function.

**Option 2: Manual configuration**

You can manually create the IDS policy configuration files by coding all of the required statements in a file. There are a large number of configuration options provided by IDS policy statements that permit advanced users to carefully fine-tune IDS policy on a per-stack basis. The information in “Defining IDS policies” on page 836 describes the procedure for creating an IDS policy by manually creating and editing the configuration files. For details about the IDS policy statements, see z/OS Communications Server: IP Configuration Reference.

**Specifying the IDS configuration file based on Policy Agent role**

The Policy Agent can act as a policy server, a policy client, or neither. For more information on these different roles, see “Policy types and infrastructure overview” on page 761. Regardless of which option is used to configure IDS policies, the resulting configuration files need to be specified using different statements, depending on the role of the Policy Agent.

- If you are using the Policy Agent as a policy client that retrieves IDS policies from the policy server, specify the configuration files using the DynamicConfigPolicyLoad statement on the policy server.
- If you are using the Policy Agent as a policy client, but the policy client does not retrieve IDS policies from the policy server, specify the configuration files using the IDSConfig statement on the policy client.
- If you are not using a policy client/policy server environment, specify the configuration files using the IDSConfig statement on the single Policy Agent.

When this information refers to configuration files, keep in mind where the files should exist, based on the role of the Policy Agent.

**Defining IDS policies**

IDS policies are stored in a Policy Agent IDS configuration file, a server that supports LDAP, or both. IDS policies are processed by Policy Agent and installed into a z/OS Communications Server TCP/IP stack. Before creating IDS policies, you should be familiar with the information about running Policy Agent, the IDS configuration file, and LDAP in Chapter 14, “Policy-based networking,” on page 761.

**Restriction:** Not all IDS policy options are available in an LDAP configuration file. Each of the policy example sections, IDS scan policy example, IDS attack policy examples, and traffic regulation policy example, indicate which policy options are not available if you are using LDAP to define IDS policy.

A conservative approach to defining IDS policy will avoid unexpected application outages and excessive rule processing. The examples here describe policies provided in the sample files shipped with the system. (See “Policy sample files” on page 773.)
IDS policy definition considerations

IDS policies can be defined with different condition type values.

**Tip:** Condition type is configured in the IDS configuration file with the ConditionType statement, and in the LDAP configuration with the ibm-idsConditionType attribute.

The supported condition types are as follows:

**SCANGLOBAL**
This policy is searched by condition type only. The highest priority scan global rule is mapped at policy change and cached. The policy defines the FastScan and SlowScan parameters, and the reporting and tracing actions to take when a scan is detected. The statistics reporting option is not applicable to scan processing. Scan processing does not impose limits, discard packets, or reset connections.

**SCANEVENT**
These policies are searched by condition type and a protocol condition of ICMP, ICMPv6, TCP, or UDP. For protocols TCP and UDP, the policy search also includes the local destination port and the bound IP address. For ICMP and ICMPv6, the highest priority scan event rule is mapped at policy change and cached. The TCP and UDP rules are mapped when a potentially countable event occurs. If the event is associated with a bound socket, the rule is cached. The policies associated with these rules define the sensitivity level to use for counting events towards the scan thresholds and the source exclusion list to use for the mapped events. Packet tracing occurs if the action associated with the scan global rule activates tracing and the sensitivity level indicates that the event is countable. The statistics reporting option is not applicable to scan processing. Scan processing does not impose limits, discard packets, or reset connections.

**ATTACK**
There are several attack types. For each attack type, the highest priority rule is mapped at policy change and cached. The reporting and statistics actions are supported for all attack types. The tracing action is supported for all attack types except EE XID flood, TCP queue size, and global TCP stall. For each attack type, the policy is searched by only condition type and attack type.

**Tip:** You can configure a discard action in the IDS configuration file as ActionType ATTACK DISCARD, and in the LDAP configuration using the ibm-idsTypeActions:LIMIT attribute.

Other supported actions are defined for each attack type. The supported attack types are:

**MALFORMED_PACKET**
Malformed packets are always discarded by the stack, even if no discard was requested by the policy.

**FLOOD**
Flood packets are always discarded by the stack, even if no discard was requested by the policy.

**ICMP_REDIRECT**
ICMP redirect packets are discarded if this policy specifies discard.

**IP_FRAGMENT**
If this policy specifies discard, fragmented datagrams are discarded if a fragmentation overlay is detected that changes the data in the packet, including changes to the length of the packet.

**RESTRICTED_IP_OPTIONS**
A list of restricted IP options is specified for this attack type. IP option 0 (end of list) and 1 (NO-OP) cannot be restricted and are ignored if specified. If this policy specifies discard, IPv4 packets are discarded if they contain an IP option that is specified in the list of restricted IP options.

**RESTRICTED_IPV6_DST_OPTIONS**
A list of restricted IPv6 destination options is required for this attack type. You cannot restrict options 0 (Pad1) or 1 (PadN); they are always allowed. If this policy specifies discard, IPv6 packets are discarded if they contain an IPv6 destination options extension header with an option that is specified in the list of restricted IPv6 destination options.

**RESTRICTED_IPV6_HOP_OPTIONS**
A list of restricted IPv6 hop-by-hop options is required for this attack type. You cannot restrict options 0 (Pad1) or 1 (PadN); they are always allowed. If this policy specifies discard, IPv6
packets are discarded if they contain an IPv6 hop-by-hop extension header with an option that is specified in the list of restricted IPv6 hop-by-hop options.

**RESTRICTED_IP_PROTOCOL**
A list of restricted IP protocols is required for this attack type. IP protocols 1 (ICMP), 6 (TCP), and 17 (UDP) cannot be restricted and are ignored if specified. If this policy specifies discard, IPv4 packets are discarded if they contain a protocol that is specified in the list of restricted IP protocols.

**RESTRICTED_IPV6_NEXT_HDR**
A list of restricted IPv6 next header values is required for this attack type. You cannot restrict next header values 6 (TCP), 17 (UDP), or 58 (ICMPv6); they are always allowed. If this policy specifies discard, IPv6 packets are discarded if they contain a next header value that is specified in the list of restricted IPv6 next headers.

**OUTBOUND_RAW**
A list of restricted IP protocols is required for this attack type. If this policy specifies discard, outbound IPv4 raw packets that meet any of the following criteria are discarded:
- Written to a raw socket that has a source IP address that is not in the stack's home list
- Fragmented by the application
- Specifies one of the ICMP reply types
- Specifies a protocol that is in the list of restricted IP protocols

**OUTBOUND_RAW_IPV6**
A list of restricted IP protocols is required for this attack type. If this policy specifies discard, outbound IPv6 raw packets that meet any of the following criteria are discarded:
- Specifies one of the ICMPv6 reply types
- Specifies one of the ICMPv6 neighbor discovery (ND) types
- Specifies one of the ICMPv6 multicast listener discovery (MLD) types
- Specifies a protocol that is in the list of restricted IP protocols

**PERPETUAL_ECHO**
A list of local UDP ports and a list of remote UDP ports is necessary with this attack type. Each port list is limited by the stack to the first 20 ports specified. The ports in each inbound UDP packet are checked against these lists. The destination port is checked against the local port list. The source port is checked against the local port list if the source IP address is in the stack's home list. Otherwise, the source port is checked against the remote port list. If this policy specifies discard, UDP packets with both ports in the checked port lists are discarded.

When defining the policy in LDAP, this attack type condition must be specified in a complex rule using CNF and multiple condition levels. The attack type condition is at one of the condition levels. There must be a list of conditions defining the local port list at a second level. There must be a list of conditions defining the remote port list at a third level. The negated flag is ignored by the stack on port list conditions.

**EE_LDLC_CHECK**
EE signaling data received on a port other than the signaling port is discarded if this policy specifies discard. An exclusion list is applied if one is configured. An EE packet is not flagged as an attack if the source IP address is found in the exclusion list.

**EE_PORT_CHECK**
EE packets with different source and destination ports are discarded if this policy specifies discard. An exclusion list is applied if one is configured. An EE packet is not flagged as an attack if the source IP address is found in the exclusion list.

**EE_MALFORMED_PACKET**
Malformed EE packets are discarded if this policy specifies discard. An exclusion list is applied if one is configured. A malformed EE packet is not flagged as an attack if the source IP address is found in the exclusion list.
EE_XID_FLOOD
An EE XID flood is detected when a large number of EE XID exchanges time out. No discard action is associated with this attack type. An exclusion list is applied if one is configured. An EE XID time out is not counted as part of flood detection if the source address of the XID is found in the exclusion list.

DATA_HIDING
If this policy specifies discard and enables checking of IP option pad fields or embedded packets within an ICMP error message, packets containing hidden data are discarded.

TCP_QUEUE_SIZE
If this policy specifies reset, the TCP connection is reset if the send, receive, or out-of-order queue becomes constrained. A queue can be constrained due to the amount of data on the queue or the age of the data on the queue. A queue size is specified in the conditions. A list of remote IP addresses, that are to be excluded when monitoring the send queue, can optionally be specified in the conditions.

GLOBAL_TCPSTALL
If this policy specifies reset, the stalled TCP connections are reset when a global TCP stall condition is detected.

TR
These policies are searched by condition type, protocol (TCP or UDP), local IP address, and local port. TCP rules are mapped when a local application does a listen on a socket or when an inbound connection handshake is completed. UDP rules are mapped when an inbound packet arrives at a local bound socket. UDP TR policy supersedes the TCPIP PROFILE setting of UDPOQUEUELIMIT for covered ports. Mapped rules are cached and associated with the bound socket.

For TCP, the policy defines the total number of allowed connections, the percentage of remaining available connections any single source IP can acquire and whether these limits are applied globally across all applications using this port number or applied individually to each application using an instance of this port number. For UDP, the policy defines which of the four available queue sizes is applied to each application using this port number. TR actions define the reporting, statistics and tracing actions for covered ports. If the policy specifies action LIMIT, connections or packets that exceed the limits are discarded.

Notes:
1. For TCP, a total connection limit or percentage available limit of zero, with an action of LIMIT effectively quiesces the application.
2. For TCP, a local host IP address cannot be specified in any condition if a TR TCP limit scope value of PORT is specified.
3. For UDP, a policy for a port without an action of LIMIT effectively makes the application unlimited.
4. Each LDAP IDS TR action must specify at least one ibm-idsTypeActions attribute.

IDS scan policy example
The goal of scan policy is to detect all scanners with potentially malicious intent while avoiding large numbers of false positives. You can make this process more efficient by reserving all unused low ports in the TCPIP profile. This will allow you to use the low sensitivity setting on scans for these ports. As you investigate the scans detected, you will initially find your own network management tools. These can be explicitly excluded. If you include UDP ephemeral ports in a high sensitivity policy, you will discover that your DNS servers show up as scanners. You can explicitly exclude these as well. To activate scan policy, a scan global rule and at least one scan event rule must be defined.

The following scan rules are defined:

• Scan Global
  Defines a global set of parameters for detecting scans, and also defines reporting parameters for scan events.
  – A Fast Scan is defined as 5 unique events in 2 minutes from a single source IP address.
- A Slow Scan is defined as 10 unique events in 480 minutes (8 hours).
- The first 200 bytes of the packet associated with each countable event will be traced.
- When a scan is detected an event will be written to syslog warning level, along with a detailed list of all the unique events included in the scan.
- No message will be written to the console.

**Scan Event Low**

Defines a set of traffic for which low sensitivity scan detection will be performed. Inbound traffic to all TCP and UDP ports between 1 and 1023 will be monitored. It is recommended that unused low ports be RESERVED in the TCPIP Profile.

**Scan Event Medium**

Defines a set of traffic for which medium sensitivity scan detection will be performed. ICMP and ICMPv6 inbound traffic will be monitored.

The following example is an IDS configuration file:

```plaintext
# Scan Policies
#-----------------------------
# Scan - IDSRule
#-----------------------------
IDSRule                    ScanEventLowTcp-rule
{                          
  ConditionType            ScanEvent
  Priority                 2
  IDSScanEventConditionRef ScanTcpLowCondition
  IDSActionRef             ScanEventLow-action
}
IDSRule                    ScanEventLowUdp-rule
{                          
  ConditionType            ScanEvent
  Priority                 2
  IDSScanEventConditionRef ScanUdpLowCondition
  IDSActionRef             ScanEventLow-action
}
IDSRule                    ScanEventMedium-rule
{

  IDSActionRef             ScanGlobal-action
  IDSScanGlobalCondition    
    {                      
      FSinterval             2
      SSInterval             480
    }
}
```

---

840  z/OS Communications Server: IP Configuration Guide
If you are using LDAP to define policy, see “IDS scan policy example” on page 1367.

Restrictions: LDAP policy cannot be used to:

- Define that ICMPv6 traffic should be monitored for scan events
- Exclude IPv6 addresses in the scan exclusion list

**IDS attack policy examples**

The goal of attack policy is to help protect your system from both known and unknown attacks and to give you timely notification when attacks do occur.

A malformed packet attack policy covers many known attacks designed to cause system failures. These packets are always discarded and rarely have legitimate source address information. Many malformed packet attacks use fragmentation to overlay header fields. The IDS fragment restriction policy is intended to protect you from unknown attacks of this type by detecting fragment overlays that change the data in a packet, including changes to the length of the packet.

Unless you know that you need to process ICMP and ICMPv6 redirect messages, you should disallow them with policy.

There are several types of flood attacks. IDS can identify TCP SYN floods and interface floods. IDS policy should be used to notify you when a flood occurs. You will need to work with your network administrators and service providers to track the flood backwards, one physical hop at a time, to locate the sources.

The IP protocol restrictions and IP option restrictions provide additional protection against future unknown attacks. These are specific to IPv4. The philosophy behind them is to disallow anything that you do not have a known reason to allow. Similar protection is provided for IPv6 by the IPv6 next header restrictions, IPv6 destination option restrictions, and IPv6 hop-by-hop option restrictions.

A data hiding attack policy provides notification when an inbound packet might contain hidden data.

The global TCP stall detection provides protection against an attack that consumes systems resources by causing many TCP connections to stall, unable to send data.
The outbound raw policy is intended to help you detect someone using your system as the base for an attack. It looks for several behaviors associated with spoofed packets. This protection applies to IPv4 sockets. The IPv6 outbound raw policy provides similar protection for IPv6 sockets.

Attack rules define the set of conditions that define what constitutes an attack for a given attack type. The highest priority rule of each attack type is used. The action associated with an attack rule defines reporting and logging options for a detected attack.

The following types of attack rules are defined in the sample policy:

• Malformed packet
  Protects against various types of known attacks based on malformed packets. Applies to IPv4 and IPv6 packets.
• Flood
  Protects against TCP SYN flood and interface flood attacks. Applies to IPv4 and IPv6 connections and interfaces.
• ICMP redirect
  Ignores received ICMP and ICMPv6 redirect messages.
• IP fragment
  Disallows fragmentation overlays that change the data in a packet, including changes to the length of the packet. Applies to both IPv4 and IPv6 packets.
• IP protocol restrictions
  Defines restricted IP protocols, and restricts everything except ICMP, TCP, and UDP. Applies to IPv4 packets only.
• IPv6 next header restrictions
  Defines restricted IPv6 next header values, and restricts everything except the following values:
  – 0 (Hop-by-hop options extension header)
  – 6 (TCP protocol)
  – 17 (UDP protocol)
  – 41 (IPv6 extension header)
  – 43 (routing extension header)
  – 44 (fragmentation extension header)
  – 50 (ESP extension header)
  – 51 (AH extension header)
  – 58 (ICMPv6 protocol)
  – 59 (No next header)
  – 60 (Destination options extension header)
  – 89 (OSPF protocol)
  – 135 (Mobility header)
  Applies to IPv6 packets only.
• IPv6 destination option restrictions
  Defines restricted options in the IPv6 destination extension header, and restricts all options except the following options:
  – 0 (Pad1)
  – 1 (PadN)
  – 4 (Tunnel encapsulation limit)
  – 5 (Router alert)
- 6 (Quick-start)
- 7 (CALIPSO)
- 138 (Endpoint identification)
- 194 (Jumbo payload)
- 201 (Home address)

Applies to IPv6 packets only.

• IPv6 hop-by-hop option restrictions

Defines restricted options in the IPv6 hop-by-hop extension header. A common IpOptionGroup is referenced by the IPv6 destination and IPv6 hop-by-hop option rules. Applies to IPv6 packets only.

• Outbound raw restrictions

Validity checking for outbound packets using raw sockets. Restricts everything except ICMP, UDP, IGMP, and OSPF1GP. Applies to IPv4 packets only.

• EE LDLC check

Validity checking of the Logical Data Link Control (LDLC) command for inbound EE packets to ensure that the packet is received on the correct port. A packet with a source IP address in the exclusion list is not checked. Applies to IPv4 and IPv6 packets.

• IPv6 outbound raw restrictions

Validity checking for outbound packets using IPv6 raw sockets. Restricts everything except ICMPv6, UDP, and OSPF protocols. Applies to IPv6 packets only.

• Data hiding checks

Applies to IPv4 and IPv6 packets.

• TCP queue size restrictions

The queue size is defined as SHORT. Applies to IPv4 and IPv6 connections.

• Global TCP stall detection

Applies to IPv4 and IPv6 connections.

• A single reusable attack action is defined and shared among all the attack rules and specifies the following actions:
  - Events are written to syslog ALERT level.
  - Events are not written to the system console.
  - The first 200 bytes of packets associated with an attack are traced.
  - Statistics are evaluated every 60 minutes and written only if an attack occurred.
  - In the IDS configuration file, Nodiscard was specified, so packets that are associated with the following attack types are not discarded:
    - ICMP redirect
    - IP fragment
    - IP protocol restrictions
    - IPv6 next header restrictions
    - IPv6 destination options
    - IPv6 hop-by-hop options
    - Outbound raw
    - IPv6 outbound raw
    - Data hiding
    - EE LDLC check
In the LDAP example in “IDS attack policy example” on page 1370, Limit was not specified, which has the same effect as Nodiscard.

- In the IDS configuration file, NoResetConn was specified, so when a TCP queue size or global TCP stall condition is detected, the TCP connections are not reset.

The following example is an IDS configuration file:

```

If you are using LDAP to define policy, see “IDS attack policy example” on page 1370.

Restriction: LDAP policy cannot be used to define rules for the following attack types:

• DATA_HIDING
• OUTBOUND_RAW_IPV6
• RESTRICTED_IPV6_DST_OPTIONS
• RESTRICTED_IPV6_HOP_OPTIONS
• RESTRICTED_IPV6_NEXT_HDR
• TCP_QUEUE_SIZE
• GLOBAL_TCP_STALL
• EE_MALFORMED_PACKET
• EE_L DLC_CHECK
• EE_PORT_CHECK
• EE_XID_FLOOD

Traffic Regulation policy examples

The goal of Traffic Regulation (TR) policy is to protect your system from usage spikes. A phased approach to determine the correct policy for your system is recommended.

To gather baseline statistics, you should first run in normal statistics mode, with the traffic regulation management daemon (TRMD) running. In normal statistics mode, the following information is provided for the port on a policy defined interval:

• Total number of connections requested during the interval
• Total number of connections closed during the interval
• The IP address of the host that requested a connection during the interval and held the highest number of concurrent connections during the interval, and the highest number of concurrent connections held by this IP address
• A suggested value for TotalConnections based on this interval
• A suggested value for Percentage based on this interval

While the baseline statistics records provide suggested policy values for the interval, you should evaluate data from multiple intervals. The values suggested are those that would avoid denying any of the connections in the interval. Choose lower values if the interval represents a workload larger than you want to allow.

After you determine the policy values to use, try running with the Log and Nolimit actions specified. Specifying the Nolimit action basically tests out the policy. The connections that would have been denied (if the Limit action was specified) are logged, but the connection is allowed to occur. After you are satisfied with the experimental policy, the policy action can be set to Limit.

The following traffic regulation TCP rules are defined:

• TRTcp-rule: Defines TCP baseline statistics gathering for the low port range.
This temporary rule provides statistical reports to determine normal traffic patterns for several applications. After the baseline values are determined, this rule should be replaced by rules that include the specific conditions to be regulated.

- **TRTcpWeb-rule**: Defines application limits and host percentage limits for a single application.
  - This rule enforces set limits.
  - The rule has a higher priority than the TR TCP rule.
  - The rule is limited to a single server application that is bound to a specific IP address.

The following example is an IDS configuration file:

```plaintext
########################################################################
# TR Policies
########################################################################

# TR - IDSRule

IDSRule TRTcpWeb-rule
{
  ConditionType TR
  Priority 7
  IDSTRConditionRef TRTcpWebCondition
  IDSActionRef TRTcpLimit-action
}

IDSRule TRTcp-rule
{
  ConditionType TR
  Priority 2
  IDSTRConditionRef TRTcpCondition
  IDSActionRef TRTcpLimit-action
  IpTimeConditionRef Time1
}

# TR - IDSTRCondition

IDSTRCondition TRTcpWebCondition
{
  Protocol Tcp
  LocalPortRange 80
  LocalHostAddr 10.14.243.87
  TRtcpTotalConnections 1000
  TRtcpPercentage 10
  TRtcpLimitScope PORT_INSTANCE
}

IDSTRCondition TRTcpCondition
{
  Protocol Tcp
  LocalPortRange 1:1023
}

# TR - IDSAction

IDSAction TRTcpLimit-action
{
  ActionType TR LIMIT
  IDSReportSet TRTcpLimitReportSet
  {
    TypeActions Log
    TypeActions Statistics
    StatType Exception
  }
}

IDSAction TRTcpLog-action
{
  ActionType TR NOLIMIT
  IDSReportSetRef LogStatReportSet
}

# IDSReportSet

IDSReportSet LogStatReportSet
{
}
```
If you are using LDAP to define policy, see “IDS TCP traffic regulation policy example” on page 1376.

**Restriction:** LDAP policy cannot be used to define TCP traffic regulation policy that specifies IPv6 addresses.

The following traffic regulation UDP rule is defined:

- TR UDP: Defines UDP queue size for the low port range.
  - This rule provides statistics reports to determine normal traffic patterns for several applications while monitoring queue sizes.

The following example is an IDS configuration file:

```plaintext
# TR Policies

# TR - IDSRule

IDSRule TRUdp-rule
{
  ConditionType TR
  Priority 2
  IDSTRConditionRef TRUdpCondition
  IDSActionRef TRUdpLogLimit-action
}

# TR - IDSTRCondition

IDSTRCondition TRUdpCondition
{
  Protocol Udp
  LocalPortRange 1-1023
  TRUdpQueueSize Long
}

# TR - IDSAction

IDSAction TRUdpLogLimit-action
{
  ActionType TR LIMIT
  IDSReportSetRef LogStatReportSet
}

# IDSReportSet

IDSReportSet LogStatReportSet
{
  TypeActions Log
  TypeActions Statistics
}
```

If you are using LDAP to define policy, see “IDS UDP traffic regulation policy example” on page 1378.

**Restriction:** LDAP policy cannot be used to define UDP traffic regulation policy that specifies IPv6 addresses.
Verification

To verify that policies are correctly defined and functioning properly, consider the following points:

- Are the policies active?
- Is the expected traffic mapping to the correct policies?
- Are the IDS Policy functions working correctly?

The following subtopics provide more details about these considerations.

Are the correct policies active?

If your policies are defined in the LDAP server, check your LDAP server log or command output for errors encountered when your policies were loaded into LDAP. Some LDAP servers treat consecutive blank lines in an LDIF file as end of file; ensure that all of the policy objects in your LDIF files are acknowledged by LDAP.

Check your Policy Agent log file for errors while processing your policy.

Use the `pasearch` command to verify that the intended policies are active and have the expected attributes for the target stack.

Is the expected traffic mapping to the correct policies?

Use the `Netstat IDS/-k SUMmary` command to ensure that the intended policy has been mapped for each of the attack types, the Scan-Global type, the Scan-Event type for protocol ICMP, and the Scan-Event type for protocol ICMPv6. See z/OS Communications Server: IP System Administrator's Commands for more information on the `Netstat` command.

These IDS functions each select the single highest priority policy for their respective types at each policy change.

Use the `Netstat IDS/-k PROTOcol TCP` and `Netstat IDS/-k PROTOcol UDP` commands to ensure that the intended Scan-Event and TR policies have been mapped to the intended local sockets.

These IDS functions select the highest priority policy for the Protocol, local Port and local IP address when there is relevant activity against the socket.

For TCP this usually entails either a listen or the completion of an inbound connection handshake. For UDP this usually entails either a bind or an inbound datagram. Scan policies are also selected on some inbound error paths.

Are the IDS policy functions working correctly?

IDS policies that include IDS actions with statistics, log, or syslog set cause the stack to make log record information available to TRMD. If TRMD is running you may run the IDS report generator `trmdstat` against the appropriate log files to produce reports on the area of interest.

TRMD

TRMD runs as an APF-authorized program. The user ID associated with TRMD must be defined with a UID of 0, or must be permitted to become a superuser by having READ access to the BPX.SUPERUSER resource in the FACILITY class. See the EZARACF member of SEZAINST for sample RACF commands for TRMD.

Use the `-p` start option or the resolver configuration file to determine the stack that TRMD uses. Ensure that you specify the `-p` start option or that the `RESOLVER_CONFIG` environment variable is correctly set before starting TRMD. A separate instance of TRMD must be run for each TCP/IP stack.

The Log records written by TRMD contain two timestamps:
• A timestamp generated when the event was detected by the stack. This timestamp is generated by the stack and is always Coordinated Universal Time (UTC).

• A timestamp that is generated when the syslogd record ID is created. This timestamp is dependent on the setting of the TZ environment variable at the time that TRMD is started. If you want this timestamp to be based on UTC, then ensure that the TZ environment variable is properly set (for example, export TZ=0) before starting TRMD.

You can set the TZ environment variable in the following ways:

• When starting TRMD from the z/OS shell:

  Export the TZ environment variable before starting TRMD; you should do this in /etc/profile or in .profile in the HOME directory. For example, if you are in the Eastern time zone in the United States:

  ```
  export TZ=EST5EDT
  ```

• When starting TRMD as a started task, use either of the following methods:
  - Specify TZ using the ENVAR parameter on the PARM statement in the started procedure. For example:
    ```
    // PARM='ENVAR("TZ=EST5EDT")'/
    ```
  - Export the TZ environment variable in a file specified with the STDENV DD statement. For example:
    ```
    // PARM='ENVAR("_CEE_ENVFILE=DD:STDENV")'/
    //STDENV DD PATH="/etc/trmd.env",PATHOPTS=(ORDONLY)
    ```

    Place the following statement in the /etc/trmd.env file:

    ```
    TZ=EST5EDT
    ```

    The use of the STDENV DD statement works well when you want to specify more than one environment variable; there is a JCL limit of 100 characters on the PARM parameter. Language Environment recommends a variable record format for the STDENV file.

You can also set the TZ environment variable for all applications in the CEEPRMxx PARMLIB member. You should define the TZ environment variable for all three LE option sets (CEEDOPT, CEECOPT, and CELQDOPT). For example:

```
CEECOPT(ALL31(ON), ENVAR('TZ=EST5EDT') )
CEEDOPT(ALL31(ON), ENVAR('TZ=EST5EDT') )
CELQDOPT(ALL31(ON), ENVAR('TZ=EST5EDT') )
```

For more information on specifying run-time options, see z/OS Language Environment Programming Guide. For details on setting the TZ environment variable, see z/OS UNIX System Services Command Reference.

If running multiple instances of TRMD, consider using the syslogd -u option when starting syslogd. The -u option causes the jobname of the application writing the log record to be included in the log record.

The TCP/IP stack must be running before TRMD can be started.

TRMD can be started from the z/OS shell or as a started task.

**Running TRMD as a started task**

A sample procedure is shipped in member EZATRMDP in SEZAINST. Follow the instructions in the sample member to define your environment.
The offset from Coordinated Universal Time (UTC) of the syslog time in the timestamp of TRMD messages is determined by the TZ environment variable. If the timestamp is required in UTC and has not been set by the TZ environment variable, specify the following definition in the TRMD procedure:

```plaintext
// PARM=('POSIX(ON) ALL31(ON)',
// 'ENVAR("LIBPATH=/usr/lib",
// "TZ=0")/-d 1')
```

To start TRMD as a started task, use the S TRMD command from the MVS console or SDSF. TRMD issues a fork, and in some cases the job name will be the original job name with a number appended. For example, S TRMD might result in the TRMD started task running under the job name TRMD1, whereas S TRMDTASK would result in the TRMD started task running under the job name TRMDTASK. Use the D A,TRMD* command to verify the job name that TRMD is running under.

If running as a started task, issue P jobname to stop TRMD.

To automatically start TRMD when the TCP/IP stack is started, add TRMD to the AUTOLOG statement in the TCP/IP profile as follows:

```plaintext
AUTOLOG TRMD JOBNAME TRMD
ENDAUTOLOG
```

**Running TRMD from the z/OS UNIX shell**

Ensure that you specify the -p start option or that the RESOLVER_CONFIG environment variable is correctly set before starting trmd.

The offset from Coordinated Universal Time (UTC) of the syslog time in the timestamp of TRMD messages is determined by the TZ environment variable. If the timestamp is to appear in Coordinated Universal Time (UTC), change the TZ specification in /etc/profile or export TZ="0" before starting TRMD.

After the appropriate environment is set up, issue the following command to start TRMD:

```plaintext
trmd
```

**Stopping TRMD**

To stop TRMD, issue the following kill command:

```plaintext
kill -s TERM pid
```

where pid is the TRMD process ID

To obtain the TRMD process ID, issue the following z/OS UNIX command:

```plaintext
ps -A
```

Debug options can also be specified when starting TRMD. See z/OS Communications Server: IP Configuration Reference for more information.

**trmdstat**

The trmdstat utility program runs from the z/OS UNIX shell. The trmdstat program reads a log file, analyzes the log records generated by TRMD, and provides summary or detailed reports based on the options specified.

The following reports can be requested:

- IDS summary of logged events
- Reports of logged connection events
- Reports of logged intrusions defined in the ATTACK policy
- Reports of logged intrusions defined in the TCP policy
• Reports of logged intrusions defined in the UDP policy
• Reports of statistics events

See z/OS Communications Server: IP System Administrator's Commands for the trmdstat command and samples of the reports generated by the trmdstat program.

Defensive filtering

An external security information and event manager, by analyzing and correlating messages from multiple sources and systems in the network, can take action to block attacks by installing defensive filters in your TCP/IP stack. A defensive filter is a rule to discard packets, and is separate from IP security filters. Filter processing matches a defensive filter rule to data traffic based on any combination of IP source or destination address, protocol, source or destination port, or direction of flow. Filter processing checks defensive filters before IP security filters.

The z/OS UNIX `ipsec` command is used to add and manage defensive filters. Defensive filters are typically added as an automated action that results from the analysis of the external security information and event manager. However, you can also add a defensive filter by manually issuing the `ipsec` command. The Defense Manager Daemon (DMD) is an integral part of managing the defensive filters.

Figure 39 on page 170 shows an overview of defensive filtering and the DMD.

For more information about defensive filters and the DMD, see Chapter 19, “Defensive filtering,” on page 1079.
Chapter 17. IP security

This topic contains a description of IP filtering, IPSec-protected traffic, and preparing and configuring a z/OS system for IP security. Various business configurations are explained, including host-to-host, host-to-gateway, gateway-to-gateway, and gateway-to-host.

Terms and concepts for IP security

The following terms and concepts are used in this information:

3DES
Also known as triple DES, this encryption method uses three DES operations on a single data block with three different keys. Provides greater security than single DES.

Active
Used in three ways:
- Describes the filter policy that is in effect (default or Policy Agent).
- Describes the state of the rules or actions that are defined in Policy Agent. These rules or actions can be active or inactive due to a time condition.
- Describes the state of a manual tunnel installed in the TCP/IP stack. A manual tunnel can be active (available for use) or inactive (not available for use).

Active IPSec policy
The policy that is in effect, either the default filter policy or the IP security filter policy.

Advanced Encryption Standard (AES)
A symmetric block cipher that can encrypt (encipher) and decrypt (decipher) information. IP security for z/OS Communications Server supports AES with a 128-bit key length.

AES Cipher Block Chaining (CBC) (AES_CBC) mode
The AES algorithm using the CBC mode. IP security for z/OS Communications Server supports AES_CBC with a 128-bit or 256-bit key length.

AES Galois Counter Mode (GCM)
The AES algorithm using Galois Counter Mode and with a 16-byte integrity check value (ICV). Galois Counter Mode is a combined-mode algorithm that performs both encryption and authentication simultaneously. IP security for z/OS Communications Server supports AES_GCM with a 128-bit or 256-bit key length.

AES Galois Message Authentication Code (GMAC)
The AES algorithm using Galois Counter Mode to encode authentication data in either AH or ESP headers. AES_GMAC functions as a combined-mode algorithm; however, it provides authentication without encryption. IP security for z/OS Communications Server supports AES_GMAC with a 128-bit or 256-bit key length.

AES Extended Cipher Block Chaining (XCBC)
The AES algorithm using the XCBC mode to encode authentication data in either AH or ESP headers, with 128-bit keys and hash truncation to 96 bits.

Asymmetric encryption
Also known as public/private key encryption, this type of encryption is performed between two parties using pairs of encryption and decryption keys.

Authentication Header (AH)
An IP protocol (51) used with an IPSec Security Association to provide authentication of IP packets.

Autoactivation
The process by which a dynamic tunnel is activated when IP security policy is installed into the TCP/IP stack, either as the result of a user action, or the result of TCP/IP or the IKED initialization.
Certificate authority
A trusted third party that verifies information that is contained in an X.509 digital certificate.

Certificate revocation list (CRL)
A time-stamped list of revoked certificates that is signed by a certificate authority.

Child Security Association
The IKEv2 name for a phase 2 Security Association.

Command-line activation
The process of activating a tunnel through the use of the `ipsec` command. Both manual and dynamic tunnels can be activated from the z/OS UNIX command line.

CRLDistributionPoints
An optional X.509 certificate extension that identifies one or more locations where the CRL for a certificate is.

Data encryption standard (DES)
A block cipher with 64-bit blocks and a 56-bit key.

Default IP filter policy
Used until the IP security filter policy is installed by Policy Agent. The default IP filter policy includes both the filter rules you define in the TCP/IP profile and the implicit default filter rules that the stack generates. The implicit default filter rules deny all traffic that does not match any configured filter rule.

Dynamic tunnel
An IPSec tunnel whose security parameters are negotiated and whose encryption keys are generated dynamically using IKE.

Elliptic curve digital signature algorithm (ECDSA)
The algorithm that is used to authenticate a remote security endpoint using ECDSA with either SHA2-256 on the P-256 curve, SHA2-384 on the P-384 curve, or SHA2-521 on the P-521 curve.

Encapsulating Security Payload (ESP)
An IP protocol (50) used with an IPSec Security Association to provide authentication and encryption of IP packets.

Hashed message authentication code (HMAC)
A one-way hash function that combines the contents of a message and a secret key to produce a hash value; used for authentication.

HMAC_MD5
HMAC using the MD5 algorithm.

HMAC_SHA1
HMAC using a SHA1 algorithm that encodes authentication data in AH or ESP headers, using a 160-bit hash value and 96-bit integrity check value (ICV).

HMAC_SHA2
HMAC using a SHA2 algorithm that encodes authentication data in AH or ESP headers and that is qualified by the length of key and hash truncation. The algorithm can have 256-bit keys and hash truncation to 128 bits, 384-bit keys and hash truncation to 192 bits, or 512-bit keys and hash truncation to 256 bits.

IKE negotiation
A process by which two communicating IKE-enabled peers agree on a set of parameters that are used to protect traffic between them. This set of parameters is collectively known as a Security Association. One peer acts as the initiator of the negotiation, the other as the responder.

IKE Security Association
The IKEv2 name for a phase 1 Security Association.

IKE tunnel
A tunnel that protects IKE phase 2 messages.

Internet Key Exchange (IKE)
A protocol for the secure generation and management of encryption keys over an existing IP network. There are two versions, commonly referred to as IKE version 1.0 (IKEv1) and IKE version 2.0 (IKEv2).
Internet Security Association and Key Management Protocol (ISAKMP)
Defines IKEv1 procedures and packet formats to establish, negotiate, modify, and delete Security Associations.

IP filter rule
A configured rule that defines the action applied to an IP traffic pattern that is encompassed by the rule. The possible actions include permit, deny, and permit with IPSec protection.

IP filter table
An ordered list of IP filter rules. When IP filtering is active on a host, the table is consulted for each IP packet that is sent or received. The action of the matching IP filter rule is enforced by the TCP/IP stack.

IPSec
A suite of protocols and standards defined by the Internet Engineering Task Force (IETF) for secure communication over an existing IP network.

IPSec tunnel
A tunnel that protects IP traffic between two endpoints using one or both of the IPSec protocols. Manual and dynamic tunnels are both instances of an IPSec tunnel.

IP security filter policy
The policy that is installed by the Policy Agent. It includes the filter rules you define in the Policy Agent configuration files and an implicit deny all rule that is generated by Policy Agent.

IP traffic pattern
The set of IP traffic attributes that can be used as input to an IP filter table query. Typically, this includes IP source address, IP destination address, source port, destination port, protocol, and direction (inbound or outbound).

Manual tunnel
An IPSec tunnel whose security parameters and encryption keys are statically configured and must be manually managed by a security administrator.

Message authentication code (MAC)
A tag derived from the contents of a message and a secret key. The tag can be used to authenticate the integrity of a message as well as the source of the message.

Message digest algorithm 5 (MD5)
A MAC algorithm that produces a 128-bit hash value.

NAT traversal (NATT)
Traversal of IPSec traffic through a NAT device.

Network address port translation (NAPT)
A technique where multiple internal IP addresses are translated into a single public IP address. As part of this translation process, the TCP and UDP ports in the packets are translated. NAPT is sometimes referred to as port address translation (PAT) or IP masquerade.

Network address translation (NAT)
Network address translation is a broad term that encompasses both a one-to-one address translation function, translating a single internal IP address to a single public IP address, and the NAPT function.

Network security services (NSS)
Services performed in support of security enforcement or management.

NSS client
Requests network security services from an NSS server. The z/OS IKE daemon can act as an NSS client for a TCP/IP stack.

NSS server
Provides network security services for one or more NSS clients.

On-demand
The process by which a dynamic tunnel is activated by outbound traffic flow without user intervention.

Phase 1
The first stage of an IKE negotiation, in which an ISAKMP Security Association is established between two IKEv1-enabled peers, or in which an IKE Security Association is negotiated between two IKEv2-
enabled peers. A phase 1 Security Association refers to IKEv1 ISAKMP SAs, as well as to IKEv2 IKE SAs.

Phase 2
The second stage of an IKE negotiation, in which an IPSec Security Association is established between two IKEv1-enabled peers, or in which a child Security Association is negotiated between two IKEv2-enabled peers. A phase 2 Security Association refers to IKEv1 IPSec SAs, as well as to IKEv2 child SAs.

Rivest Shamir Adleman (RSA)
An asymmetric key encryption method, in which the key that is used to encrypt data is different than the key that is used to decrypt the data. RSA can be used for encryption, or to authenticate a digital signature.

Secure hash algorithm 1 (SHA1)
A MAC algorithm similar to MD5, but more secure. This algorithm produces a 160-bit hash value.

Secure hash algorithm 2 (SHA2)
A MAC algorithm similar to SHA1, but more secure. This algorithm produces a 256-bit, 384-bit or 512-bit hash value.

Security Association (SA)
An agreement between two IPSec-enabled hosts that describes the type of data to protect and the methods that are used to protect the data. IKE creates a phase 1 Security Association to protect IKE messages (also known as the ISAKMP Security Association or the IKE Security Association), and a phase 2 Security Association to protect data traffic (also known as the IPSec Security Association or the child Security Association).

Symmetric encryption
Encryption that is performed between two parties sharing the same encryption key. Also known as secret key encryption.

Transport mode encapsulation
A process used to construct IPSec packets by inserting one or more additional IPSec headers between the IP header to be protected and the IP payload of the packet to be protected.

Tunnel
A secure logical connection or channel that is defined by a collection of Security Associations that define the security parameters protecting traffic between two endpoints.

Tunnel activation
The process by which a tunnel becomes active or usable. For dynamic tunnels, this process involves initiating an IKE negotiation.

Tunnel mode encapsulation
A process used to construct IPSec packets by creating a new IP header with an IP payload consisting of the entire IP packet being protected, and then inserting one or more additional IPSec headers between the new IP header and its IP payload (that is, the original IP packet).

UDP encapsulation
A process used to construct IPSec packets by first applying tunnel mode encapsulation or transport mode encapsulation to an IP packet to be protected by the ESP protocol, and then inserting a UDP header between the IP header and the ESP header.

Virtual private network (VPN)
A logical network of connected network nodes that communicate through secure channels (tunnels), typically by using the IPSec protocols (AH and ESP).

X.500 distinguished name
A collection of X.509 values, such as common name, host name, organization, organizational unit, and so on, that is stored in an X.509 digital certificate. An X.500 distinguished name is used as a globally unique identifier for the owner.

X.509 digital certificate
A set of information in the X.509 standard containing various attributes about an entity, including identity information and a public key that is used for encrypted communications with that entity.
Terminology conventions for IP security

The following terminology conventions are used throughout this information when referring to z/OS IP security:

**IP security**
The z/OS Communications Server function.

**IPSec**
The protocol suite.

**ipsec**
The action associated with an IP filter action, or the z/OS UNIX System Services command.

**IPSEC**
The statement in the TCP/IP profile.

**IPSECURITY**
The parameter on the IPCONFIG statement in the TCP/IP profile.

**NAT**
The general network address translation function. NAT encompasses both one-to-one address translation and network address port translation.

**NAPT**
Network address port translation. This term is used when information is specific only to this form of NAT.

Commands used to administer IP security

The following commands are used to administer IP security. For more information on these commands, see z/OS Communications Server: IP System Administrator's Commands.

**certbundle**
Use the z/OS UNIX System Services `certbundle` command to create a certificate bundle file that contains certificate and CRL information.

**ipsec**
Use the z/OS UNIX System Services `ipsec` command to display information about active filters and Security Associations, and to control aspects of Security Association negotiation. The `ipsec` command is used to:

- Display filters that are active in the stack
- Revert to default IP filter policy, as defined in the TCP/IP profile
- Reload IP security policy, as defined in the Policy Agent configuration files
- Activate Security Association negotiations
- Display existing phase 1 Security Associations
- Display existing phase 2 Security Associations
- Display remote port mappings used with NAT traversal configurations
- Display network security configuration information for the active stacks on the local system
- Display information for each NSS IPSec client that is currently connected to the NSS server
- Refresh existing phase 1 Security Associations
- Refresh existing phase 2 Security Associations
- Deactivate existing phase 1 Security Associations
- Deactivate existing phase 2 Security Associations
- Test for a filter rule match for a given set of IP traffic characteristics
Authority to use the **ipsec** command is controlled through RACF. There are two distinct types of SERVAUTH profiles that define access to the **ipsec** command, one for display capabilities and one for control capabilities.

**Tip:** Many of the tasks, examples, and references in this information assume that you are using the z/OS Security Server (RACF). References to RACF apply to any other SAF-compliant security products that contain the required support. If you are using another security product, read the documentation for that product for instructions on task performance.

For the steps to configure access control to the **ipsec** command, see Appendix E, “Steps for preparing to run IP security,” on page 1331.

For detailed syntax and usage, and how to control access of the **ipsec** command, see z/OS Communications Server: IP System Administrator's Commands.

**pasearch**

Use the **pasearch** command to display Policy Agent information that is defined in the Policy Agent configuration files, including IP security and other types of policies. The options that are related to IP security include the ability to view IP security policy rules and actions, both active and inactive, for any TCP/IP stack for which policies have been defined and that is IPSECURITY-enabled.

If the user of the **pasearch** command is not a superuser, authority is controlled through RACF.

For detailed syntax and usage of the **pasearch** command, see z/OS Communications Server: IP System Administrator's Commands.

**MODIFY**

Use the **MODIFY** console command to have:

- The IKE daemon reread the IKED configuration file
- Policy Agent reread the Policy Agent configuration files

For detailed syntax and usage of the **MODIFY** command, see z/OS Communications Server: IP System Administrator's Commands.

**Netstat**

Use the **Netstat** command to display the following information:

- IPSECURITY enablement for a particular stack (Netstat CONFIG/-f)
- SecurityClass (SECCLASS) for a specific interface (Netstat DEVLINKS/-d)

For detailed syntax and usage of the **Netstat** command, see z/OS Communications Server: IP System Administrator's Commands.

**Overview of using IP security**

z/OS Communications Server provides the ability to control and monitor network traffic on one or more TCP/IP stacks on a z/OS system. IP security for z/OS Communications Server supports IP filtering, IPSec, and Internet Key Exchange (IKE). IP security for z/OS Communications Server supports two versions of the IKE protocol: IKEv1 and IKEv2. See “Dynamic key management - IKE and IPSec negotiations” on page 898 for more information.

IP security policy can be used for the following protection:

- Protect a secure host on an internal network from unwanted network traffic
- Provide protection for traffic between partner companies over connected networks
- Allow secure sending of data over the Internet by providing IPSec virtual private network (VPN) support

These features are implemented in the IP layer on a per packet basis, and thus are available to any network application without requiring any special modifications. Applications can also implement their own additional security features as necessary, on top of the underlying IP security.
IP security policy is enabled, enforced, managed, and monitored through a coordinated effort of several z/OS Communications Server components:

- **Policy Agent**
  The Policy Agent is used to configure IP security on a z/OS system. It reads the configuration files that contain the IP security policy configuration statements, checks them for errors, and installs them into the IKE daemon and the TCP/IP stack.

- **Internet Key Exchange daemon (IKED)**
  The Internet Key Exchange daemon is responsible for retrieving IP security policy from Policy Agent, and dynamically managing keys that are associated with dynamic IPSec VPNs. This daemon also provides network management capabilities for IP security aspects of local TCP/IP stacks.

- **Network Security Services daemon (NSSD)**
  The Network Security Services daemon provides the NSS server functionality. It provides the NSS IPSec certificate service to perform digital signature creation and verification operations on behalf of NSS IPSec clients. The NSS IPSec certificate service is used by the IKED during phase 1 negotiations when digital signature authentication is required.

- **TCP/IP stack**
  The stack maintains a list of currently active IP filters and IPSec Security Associations, actively filters network traffic, controls encryption and decryption of network data, and maintains counters that are associated with an IPSec Security Association lifetime.

- **Traffic Regulation Manager daemon (TRMD)**
  The Traffic Regulation Manager daemon is responsible for logging IP security events that are detected by the stack, including IP filter events, updates to IP security policy, and the creation, deletion, and refresh of IPSec Security Associations.

- **System logging daemon (syslogd)**
  The system logging daemon manages the logging of messages and events for all of the other components, including where the log messages are written.

These components provide a combination of technologies that form the basis of IP security:

- IP filtering
- IP filter logging
- Data encryption and authentication

**FIPS 140 mode and IP security**

The Internet Key Exchange daemon (IKED), the network security services daemon (NSSD), and the TCP/IP stack components perform a wide variety of cryptographic operations for IP Security. The IKED and the NSSD manage cryptographic keys and digital signatures and perform hashes for authentication. The IKED and the TCP/IP stacks perform encryption and decryption of messages that flow over the IPSec tunnels. Architectural enhancements to the IKE protocols periodically introduce new cryptographic algorithms for performing hashes and encryption.

Federal Information Processing Standards (FIPS) document 140 (FIPS 140) provides a higher degree of assurance of the integrity of cryptographic operations by placing restrictions on the cryptographic components and the operations performed by these components. Weaker algorithms are forbidden and all the operations must be performed by cryptographic modules that are contained within a well defined cryptographic boundary.

You can configure the IKED, the NSSD, and the TCP/IP stack components to operate in FIPS 140 mode. When you do, you restrict the cryptographic algorithms they support, and you modify their interactions with each other and with the other hardware and software components of the z/OS system related to cryptography, such as Integrated Cryptographic Services Facility (ICSF) and System SSL.
In FIPS 140 mode, the IKED, the NSSD, and the TCP/IP stacks enforce the following restrictions on the cryptographic algorithms that can be used for IP security:

- You cannot use the DES encryption algorithm.
- You cannot use the HMAC-MD5, HMAC-MD5-96, AES128-XCBC, and AES128-XCBC-96 algorithms for authentication or pseudo-random function.
- You cannot use Diffie-Hellman groups 1, 2, and 5.
- You cannot use certificates for RSA signature authentication that have key lengths less than 1024 bits.
- You cannot use pre-shared keys whose length is less than half the key size of the chosen HowToAuthMsgs (IKEv1) or PseudoRandomFunction (IKEv2) algorithm.

When the FIPS 140 mode is configured for a TCP/IP stack, the Policy Agent enforces some of the FIPS 140-related restrictions when it parses the IP security policy files. Other restrictions are enforced when dynamic tunnels are being activated, after the FIPS 140 mode of all of the relevant software components (the IKED and the NSSD) is known.

You configure FIPS 140 mode independently for each of the IKED, the NSSD, and the TCP/IP stack components. ICSF and System SSL must also be configured to support FIPS 140. If you use FIPS 140 mode in some components and not others, the resulting system might not operate in FIPS 140 mode. The components that are configured to use FIPS 140 mode can use cryptographic services only from components that are also operating in FIPS 140 mode, so the FIPS 140 mode mismatch can cause functional problems.

- If a TCP/IP stack is configured to use FIPS 140 mode, but the IKED is not, the IKED does not perform any dynamic VPN tunnel activations for the stack. The IKED performs many cryptographic operations on behalf of the stack during tunnel activation.

**Rule:** Whenever the stack is configured for FIPS 140 mode, also configure FIPS 140 mode for the IKED.

- If the IKED and the TCP/IP stacks it supports are configured to use FIPS 140 mode, but the NSSD is not, the IKED cannot use the NSS IPSec certificate service for its stacks. Because the IKED must use the NSS IPSec certificate service to create and verify digital signatures for IKEv2 tunnels, this FIPS 140 mode mismatch prevents activation of any IKEv2 tunnels that use digital signature authentication.

**Rule:** Whenever the IKED is configured for FIPS 140 mode, also configure FIPS 140 mode for the NSSD.

- If you have a sysplex that is configured for Sysplex-Wide Security Associations (SWSA), and the distributor stack is not configured to use FIPS 140 mode, then it will not be able to successfully distribute tunnels to target stacks that are configured in FIPS 140 mode.

**Rule:** Whenever you have target stacks that are configured in FIPS 140 mode, first configure FIPS 140 mode for the distributing stack.

When possible, you should enable FIPS 140 mode for the IKED, the NSSD, and the TCP/IP stacks all at once. If you must implement FIPS 140 support in stages, enable FIPS 140 mode in the components in the following order:

1. Configure FIPS 140 mode in the NSSD. If the NSSD is configured in FIPS 140 mode and the IKED and the TCP/IP stacks are not, the IKED still uses the NSS IPSec certificate service provided by the NSSD. Note that the NSSD creates and verifies signatures only for certificates that conform to FIPS 140 restrictions, even if the IPSec client is not operating in FIPS 140 mode.

2. Configure FIPS 140 mode in the IKED. When the NSSD and the IKED are both in FIPS 140 mode, but the stacks are not, dynamic VPN tunnels can be activated and data can flow, as long as those tunnels follow the FIPS 140 cryptographic algorithm restrictions.

3. If you are using SWSA in a sysplex, configure FIPS 140 mode in the distributor stack of the sysplex.

4. Configure FIPS 140 mode in all other TCP/IP stacks.

Enabling FIPS 140 mode on a system can affect performance. For example, you might have to change from using a weak encryption algorithm to using one that requires more processing to perform. Even if no algorithm changes are necessary, the IKED, the NSSD, and the TCP/IP stacks perform their cryptography operations in a different way when FIPS 140 mode is enabled than when it is not enabled, because FIPS...
140 imposes additional self-verification requirements and access restrictions, and because hardware accelerated implementations of some cryptographic operations might not be available in FIPS 140 mode.

**Steps for configuring IP security to support FIPS 140 mode**
Configure IP security to support FIPS 140 mode on each system and stack that needs to use FIPS 140 mode. If you are using Sysplex-Wide Security Associations (SWSA), perform these steps first on your distributor and backup stacks, and then on each of your target stacks.

**Procedure**
Perform the following steps to configure IP security to support FIPS 140 mode:

1. Ensure that Integrated Cryptographic Services Facility (ICSF) is started and configured to support FIPS 140.
   
   **Requirement:** ICSF must be active before starting the IKE daemon or NSS server configured in FIPS 140 mode. For information about enabling ICSF to support FIPS 140-2, see the topic about operating in compliance with FIPS 140-2 in z/OS Cryptographic Services ICSF Writing PKCS #11 Applications.
   
   **Tip:** You do not need to create TKDS data sets in order for IP security to use ICSF.
   
   For more information about enabling FIPS 140 mode for ICSF, see z/OS Cryptographic Services ICSF Administrator's Guide.

2. Ensure that one of the following conditions are true:
   
   - The SAF class CRYPTOZ is not active.
   - No SAF profile exists for the FIPSEXEMPT.SYSTOK-SESSION-ONLY resource in the CRYPTOZ class.
   - The IKED, the NSSD, and the TCP/IP stacks that are configured in FIPS 140 mode have no access (NONE) to the SAF resource FIPSEXEMPT.SYSTOK-SESSION-ONLY in the CRYPTOZ class.
   
   **Tip:** A single z/OS system can support multiple TCP/IP stacks, and you can configure some TCP/IP stacks with FIPS 140 support and others without FIPS 140 support. The stacks that are configured in FIPS 140 mode must not have access to the SAF resource FIPSEXEMPT.SYSTOK-SESSION-ONLY in the CRYPTOZ class.

3. Ensure that System SSL FIPS 140 support is available and configured. For more information, see the information about System SSL and FIPS 140-2 in z/OS Cryptographic Services System SSL Programming.

4. If you are using network security services (NSS), configure NSS to support FIPS 140.
   
   You can configure FIPS 140 by specifying Yes as the FIPS140 value in the NSS configuration file (for example, nssd.conf). In the IBM Configuration Assistant for z/OS Communications Server, configure the FIPS 140 option in the Advanced Server Settings for NSS in the NSS perspective.
   
   After you have configured FIPS 140, restart the NSS daemon if it was active.
   
   **Tip:** If TCP/IP is enabled for FIPS 140 but the NSSD is not, then the NSSD cannot provide NSS certificate services to the TCP/IP stack.

5. Configure IKE to support FIPS 140.
   
   You can configure FIPS 140 by specifying Yes as the FIPS140 value in the IKED configuration file (for example, iked.conf). In the IBM Configuration Assistant for z/OS Communications Server, configure the FIPS 140 option in the Advanced IKE Daemon Settings in the IPSec perspective.
   
   After you have configured FIPS 140, restart the IKE daemon if it was active.
   
   **Tip:** If TCP/IP is enabled for FIPS 140 but the IKED is not, then the IKED will not negotiate dynamic VPN tunnels for that TCP/IP stack.

6. Configure the TCP/IP stack to support FIPS 140.
   
   You can configure FIPS 140 by specifying FIPS140 Yes on the IpFilterPolicy statement in the IPSec policy file for the stack. In the IBM Configuration Assistant for z/OS Communications Server, configure the FIPS 140 option in the Advanced Stack Settings in the IPSec perspective.
   
   After you have configured FIPS 140, restart the stack if it was active.
Configuring IP security

You configure z/OS IP security using an extensive set of configuration statements and parameters coded into a flat file, which is parsed by the Policy Agent to establish the set of IP security requirements for each TCP/IP stack. IBM provides two alternatives for creating the Policy Agent configuration files:

- “Configuring IP security using the IBM Configuration Assistant for z/OS Communications Server” on page 864
- “Configuring IP security using manual configuration” on page 864

Configuring IP security using the IBM Configuration Assistant for z/OS Communications Server

The IBM Configuration Assistant for z/OS Communications Server, an optional GUI-based tool, provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the IBM Configuration Assistant for z/OS Communications Server to generate the Policy Agent and IKE daemon configuration files.

The IBM Configuration Assistant for z/OS Communications Server is a z/OS Management Facility (z/OSMF) task. z/OSMF provides a web browser interface for a variety of z/OS system management functions. When you invoke the IBM Configuration Assistant for z/OS Communications Server in z/OSMF, the IBM Configuration Assistant for z/OS Communications Server runs natively in the z/OS system and you can access it through a web browser.

Through a series of wizards and online help panels, you can use the IBM Configuration Assistant for z/OS Communications Server to create IP security configuration files for any number of z/OS images with any number of TCP/IP stacks per image. Using the IBM Configuration Assistant for z/OS Communications Server, there are four types of reusable objects:

- Traffic descriptors that define the IP traffic type, such as TCP or UDP
- Security levels that define the different ways to protect data, such as the encryption level
- Requirement maps that map traffic descriptors to security levels
  - A single requirement map should contain a complete set of security requirements that will govern the level of security for multiple IP traffic types.
- Address groups that define a set of addresses to be used in an IP filter rule

For each TCP/IP stack, you create a set of connectivity rules that indicate the data endpoints and indicate which requirement map will govern security between the data endpoints.

The IBM Configuration Assistant for z/OS Communications Server comes with a number of IBM-supplied traffic descriptors, security levels, and requirement maps that are easily applied to an existing network topology, or the IBM-supplied definitions can be used as the basis for your own set of reusable objects.

The IBM Configuration Assistant for z/OS Communications Server can dramatically reduce the amount of time that is required to create IP security policy files, contributing to ease of configuration and maintenance. Because of the inherently complex nature of z/OS security, use of the GUI is encouraged to ensure that you have a consistent and easily manageable interface for implementing IP security.

This information primarily describes option 2, manual configuration. However, if you are using the IBM Configuration Assistant for z/OS Communications Server, reading this information will help you understand security concepts and the relationship between Policy Agent and IP security function.

Configuring IP security using manual configuration

You can manually create the IP security policy configuration files by coding all of the required statements in a z/OS UNIX file or MVS data set. There are a large number of configuration options provided by IP security policy statements that permit advanced users to carefully fine-tune IP security policy on a per-stack basis. This information describes the procedure for creating an IP security policy by manually creating and editing the configuration files. There are examples that step through the process of creating a configuration file that includes zones corresponding to various security models. For details about the configuration statements and parameters, see the Policy Agent and policy applications topic in z/OS Communications Server: IP Configuration Reference.
Specifying the IP security configuration file based on Policy Agent role

The Policy Agent can act as a policy server, a policy client, or neither. For more information on these different roles, see “Policy types and infrastructure overview” on page 761. Regardless of which option is used to configure IP security policies, the resulting configuration files need to be specified using different statements, depending on the role of the Policy Agent.

- If you are using the Policy Agent as a policy client that retrieves IP security policies from the policy server, specify the configuration files using the DynamicConfigPolicyLoad statement on the policy server.
- If you are using the Policy Agent as a policy client, but the policy client does not retrieve IP security policies from the policy server, specify the configuration files using the IPSecConfig statement on the policy client.
- If you are not using a policy client/policy server environment, specify the configuration files using the IPSecConfig statement on the single Policy Agent.

When this information refers to configuration files, keep in mind where the files should exist, based on the role of the Policy Agent.

IP filtering

IP filtering controls the flow of network traffic. An administrator can deny or allow any given network packet into or out of a z/OS system with an IP security policy.

Filter rules and actions

The IP security policy enables a z/OS system to classify any IP packet that comes across a network interface and take specific action according to a predefined set of rules. The set of properties that identify a packet, together with the action to be performed on it, is known as an IP filter rule. The rule can be used to filter out unwanted packets from the network stream, while allowing others. The collection of all filter rules comprise the IP filter table. The IP filter table contains all of the IP filter rules in the order in which they were configured. IP filter rules are configured using the IpFilterRule statement in an IP security policy configuration file. For more details about the IpFilterRule statement, see z/OS Communications Server: IP Configuration Reference.

For example, a simple filter table might have the following set of rules:

1. Allow Telnet traffic from IP address A.
2. Allow FTP traffic from IP address B and IP address C.
3. Allow any traffic from subnet D, but ensure that it is encrypted.
4. Allow encrypted traffic from any location if the remote IKE identity is a corporate email address.
5. Allow outbound connections to anywhere.
6. Deny anything that does not match the previous rules.

This set of rules would be considered to be a filter table consisting of six rules.

The filter table that is configured for a particular installation reflects the security needs for that site. The rules can be restrictive or permissive, as the security policy allows. Normally the rules would deny anything not explicitly permitted, a configuration known as a default-deny policy, in which rules are added as necessary to allow only crucial network traffic. In a default-deny environment, the absence of any IP filter rules essentially isolates the system from the network. The alternative, a default-allow policy, allows all network traffic in the absence of any configured rules. Specific rules can be added as needed to deny unwanted or potentially malicious traffic. A default-deny policy is considered to be much more secure.

Rule: A z/OS Communications Server TCP/IP stack that is configured for IP security follows a default-deny policy by default, in the absence of any configured filter rules.

IP filter tables can grow very complex, and in many implementations are difficult to maintain. However, the configuration mechanism that is provided by IP security enables you to attach meaningful descriptors
to rules, hosts, and other configured items, which makes keeping track of complex filter tables an easier task.

To protect data between hosts, hosts must agree on what type of traffic to protect, and how to protect that traffic. These IP traffic pattern definitions are stored in the locally configured security policy and installed in the IP filter table, which is consulted for each IP packet that enters or leaves the system. When a packet matches one of the rules in the IP filter table, the policy determines what action is taken for that packet. IP filter actions are configured using the IpGenericFilterAction statement in an IP security policy configuration file. For more details about the IpGenericFilterAction statement, see z/OS Communications Server: IP Configuration Reference.

On a z/OS stack that has IPCONFIG IPSECURITY configured (and perhaps also has IPCONFIG6 IPSECURITY configured) and an active IP security policy, there are three possible actions:

- Deny the packet.
- Permit the packet.
- Permit the packet with IPSec protection.

If the action that is associated with the filter rule is an ipsec action, the packet is subject to the application of IPSec authentication and encryption before it is received or sent. Any packet that matches a filter rule with an ipsec action is processed using the IPSec protocols, either Authentication Header (AH), Encapsulating Security Payload (ESP), or both, depending on the locally configured policy. z/OS IP security requires that data authentication be done if the filter rule specifies an ipsec action.

**Filtering criteria in an IP packet**

IP packets match IP filters based on a number of selection criteria. There are five primary pieces of information that are gathered from the IP packet, commonly referred to as a 5-tuple:

- **Source address**
  An IP packet can be filtered based on the source address located in the IP header of the packet.

- **Destination address**
  An IP packet can be filtered based on the destination address located in the IP header of the packet. For IPv6 packets that contain a type 0 or type 2 routing header, the stack performs IP filtering using the final destination address of the packet based on the routing header contents, not on the destination address in the IP header.

- **Protocol**
  An IP packet can be filtered based on the protocol in the IP header of the packet.

- **Source port**
  If the protocol in an IP packet is TCP or UDP, the packet can be filtered based on the source port in the TCP/UDP header of the data portion of the packet.

- **Destination port**
  If the protocol in an IP packet is TCP or UDP, the packet can be filtered based on the destination port in the TCP/UDP header of the data portion of the packet.

**Additional filtering criteria based on protocol**

The following criteria are some additional filtering criteria that are based on protocol:

- **ICMP type and code**
  If the protocol in an IP packet is ICMP or ICMPv6, the packet can be filtered based on the ICMP type and code located in the ICMP header of the data portion of the packet.

  **Guideline:** Typically, if an ICMP error is generated for a packet that arrived over a Security Association, and there is no matching rule for the ICMP error, z/OS Communications Server attempts to send the ICMP packet over the same Security Association that carried the original packet. If you want to disable this processing, you must code a rule that covers ICMP errors.
• OSPF type
  If the protocol in an IP packet is OSPF, the packet can be filtered based on the OSPF type located in the OSPF header of the data portion of the packet.

• Mobility header type
  If the protocol in an IP packet is IPv6 mobility header, the packet can be filtered based on the mobility header type located in the mobility header of the data portion of the packet.

Additional filtering criteria based on network attributes

Some filtering criteria are inferred from the external characteristics of the IP traffic, rather than being found in the actual IP packet. The following additional attributes are used to distinguish IP packets:

• Direction
  The direction of an IP packet is either inbound or outbound.

• Routing
  The routing attribute of an IP packet is either local or routed. IP packets are considered local if either of the following conditions is true:
  – The packet is inbound and the destination address in the IP packet exists on the IPSECURITY stack.
  – The packet is outbound and the source address in the IP packet exists on the IPSECURITY stack.
  Otherwise the IP packet is considered routed.

• Security class
  Each non-virtual interface on a z/OS system is assigned a security class. The security class of an IPv4 interface is determined by the SECLASS parameter that is coded on the LINK statement or the DYNAMICXCF parameter of the IPCONFIG statement in the TCP/IP profile. The security class of an IPv6 interface is determined by the SECLASS parameter that is coded on the INTERFACE statement or the DYNAMICXCF parameter of the IPCONFIG6 statement in the TCP/IP profile. The value of SECLASS is a number in the range 1-255. If SECLASS is not specified for an interface, the interface has a default security class of 255.

  Each IP packet entering or leaving the system inherits the security class of the interface that it traverses:
  – For inbound traffic, this is the interface on which the packet arrived.
  – For outbound traffic, this is the interface over which the packet is sent.

  The value for SECLASS has no inherent meaning. A SECLASS of 255 is no more or less secure than a SECLASS of 1. You can optionally assign a SECLASS value either to uniquely identify an interface, or to group interfaces with similar security requirements, based on site policy. Consequently, this attribute can be used as an additional criterion for IP filtering. Security class can be used to define broad filter rules that encompass all of the IP traffic that uses a group of interfaces without explicit knowledge of network addressing, or to ensure that an IP packet arrived on a valid interface.

  For example, as shown in Figure 104 on page 868, consider a z/OS system with three physical interfaces that are assigned the following security classes:

<table>
<thead>
<tr>
<th>Interface</th>
<th>Security Class</th>
</tr>
</thead>
<tbody>
<tr>
<td>I1</td>
<td>10</td>
</tr>
<tr>
<td>I2</td>
<td>20</td>
</tr>
<tr>
<td>I3</td>
<td>20</td>
</tr>
</tbody>
</table>
All IP packets from NET1 and NET2 have the same security class (10), and all IP packets from NET3 and NET4 have the same security class (20). Even though each interface on the z/OS system can reach multiple networks, you can configure a single IP filter rule that matches all of the IP traffic from NET3 and NET4 without explicitly identifying any attributes of the IP packets, other than security class. For instance, if NET3 and NET4 are trusted internal networks in which you want to allow all network traffic, you can configure one IP filter rule permitting all traffic with a security class of 20, without regard to IP address.

An IP filter using security class as a criterion is not limited to scenarios in which the IP addresses are ignored. To counter IP address spoofing, IP filter rules can take into account both security class and IP address. IP address spoofing involves the creation of an IP packet whose source address has been modified to reflect an address other than that of the originator. Because routers ignore the source address when making routing decisions, the modified IP packet can still reach its destination. An IP packet whose source IP address has been spoofed is usually not legitimate and is often used in a malicious manner. IP filtering can counter an attempt to spoof a source IP address by ensuring that an IP packet arrived on a valid network interface. For instance, any inbound packet that has a source address of an internal network node, but entered the system through an external interface, is probably spoofed and should be denied.

**Rule:** The SecurityClass parameter cannot be used on an IpFilterRule statement with a dynamic ipsec action. The IKE protocols do not provide for the negotiation of SecurityClass, and therefore it cannot be used as a selection criterion for a Security Association. The SecurityClass parameter can be configured only for an IpFilterRule statement that has an action of permit, deny, or manual ipsec. Coding a SecurityClass parameter with a value other than 0 on a dynamic ipsec rule is considered a configuration error.

**Guidelines:**

- If there are multiple interfaces by which a packet can reach its destination, the SECCLASS values for the interfaces and the filter rules should be consistent. If a packet could reach its intended destination by traversing one of a number of interfaces, the SECCLASS values and the related filter rules should account for the possibility of alternate routing.

- If the same IPv6 link-local address exists in multiple LANs in your network and you want to define filter rules to distinguish these IP addresses, configure different SECCLASS values for the interfaces onto these LANs to make the filter rules unique. However, if you are using dynamic IPSec for link-
local addresses, you cannot use SECCLASS values to make the filter rules unique, so you must ensure that there are no overlapping or duplicate link-local addresses.

For more details about the SecurityClass parameter on the IpService statement, the SECCLASS parameter on the LINK and INTERFACE statements, and the SECCLASS keyword on the DYNAMICXCF parameter of the IPCONFIG and IPCONFIG6 statements, see z/OS Communications Server: IP Configuration Reference.

- Remote IKE identity

For traffic that is protected by IPSec, the remote IKE identity can be used as a filtering criterion. This is particularly useful in cases where a client is roaming or mobile and does not have a fixed IP address, but has a known authenticated IKE identity.

Filter rules with a remote IKE identity often have wildcard IP addresses that are not very specific, because mobile users can connect from a variety of locations.

Guidelines:

- Consider placing filter rules with a remote IKE identity near the bottom of your IP filter policy, so that other traffic has optimal filter searching. Because the wildcard IP addresses are not very specific for these rules, much IP traffic needs to be compared against these rules to test whether the traffic matches the rule.

- Consider whether the mobile client's traffic might intersect with other filter rules; for example, when a mobile user occasionally brings their laptop into the office. If you choose to permit the user to continue to establish their IPSec connection while in the office, then you should order the remote identity filter rules in your IP filter policy so that they precede the office network filter rules.

**IP traffic patterns**

The information that is gathered from an IP packet can be used to identify a specific type of network traffic, based on common Internet protocols. For example:

- Web traffic to a server consists of TCP packets inbound to and outbound from port 80.
- TN3270E Telnet server traffic consists of TCP packets inbound to and outbound from port 23.
- IKE traffic consists of UDP packets inbound from and outbound to port 500. In addition, if NAT traversal is enabled, IKE traffic can use UDP port 4500.
- Ping (IPv4) consists of ICMP packets outbound with type 8, code 0 (echo request), and inbound with type 0, code 0, (echo reply).
- Ping (IPv6) consists of ICMPv6 packets outbound with type 128, code 0 (echo request), and inbound with type 129, code 0, (echo reply).

The IpService statement groups these attributes into definitions of common traffic patterns that can subsequently be incorporated in an IP filter rule. The sample configuration file /usr/lpp/tcpip/samples/pagent_CommonIPSec.conf provides definitions for many of the common traffic patterns that are seen on a typical z/OS server.

For more details about the IpService statement, see z/OS Communications Server: IP Configuration Reference.

**Routed traffic and fragmented packets**

Fragmented packets are problematic for IP security implementations because transport layer headers (UDP, TCP, and so on) are not present in every fragment. For some packet fragments, the transport layer selector values (for example, UDP ports, ICMP type and code) are indeterminate, which complicates IP packet filtering. In the case of IPv6, a fragment's IP protocol value might also be indeterminate.

Tip: z/OS Communications Server filters fragmented packets only for routed traffic. For all local traffic, z/OS Communications Server performs filtering on the fully assembled packet.
Because some packet fragments do not contain the transport layer header and cannot be filtered based on transport layer selector values, z/OS Communications Server enforces the following restriction for routed traffic.

**Restriction:** All routed traffic between two endpoints must be filtered in the same manner without regard to TCP or UDP port, ICMP or ICMPv6 type and code, or OSPF and MIPv6 type.

**Guideline:** To perform more granular filtering for this traffic, enforce a port-specific filtering policy, or a type-specific and code-specific filtering policy, at the final destination for this IP traffic.

z/OS Communications Server supports the specification of Opaque for matching indeterminate IPv6 protocol values in packet fragments. Packets that have an indeterminate value match filter rules only when Opaque or Any is specified.

z/OS Communications Server also supports explicit matching on fragmented packets. The IpService policy object’s fragment specification can be used to match any fragmented packet, even if the packet’s selector values are known. Explicit matching can be used to deny all fragmented packets in situations in which they are not part of normal traffic patterns and are considered to be a security risk.

**Conditionally controlling IP filters**

When IP filters from IP security policy files are installed into the stack, they are always active by default. Depending on the business need, this might not always be desirable. For instance, you might want to restrict certain types of IP traffic to a specific time, day, or week. IP security provides this flexibility by allowing you to specify a time condition for an IP filter rule. The IpTimeCondition statement specifies when an IP filter or a manual IPsec tunnel is active. You can prescribe not only what traffic is allowed, but when that traffic is allowed, in a way that is not disruptive and without having to edit the IP security policy files.

For more details about the IpTimeCondition statement, see z/OS Communications Server: IP Configuration Reference.

**Special considerations when using IP security for IPv6**

This topic describes considerations for using IP security for IPv6.

**Neighbor discovery and multicast listener discovery**

For IPv6, TCP/IP uses the neighbor discovery protocol, which provides the following functions:

- Address resolution (neighbor solicitations and neighbor advertisements to perform ARP functions for IPv6)
- Duplicate address detection (neighbor solicitations and neighbor advertisements to ensure unique IP addresses)
- Router discovery (router solicitations and router advertisements to keep track of neighboring routers)
- Neighbor unreachability detection (to keep track of the reachability of neighbors)

TCP/IP also uses multicast listener discovery (MLD), which notifies routers that nodes are ready to receive multicast packets.

Neighbor discovery and MLD are implemented using ICMPv6 packets.

When the stack is enabled for IP security for IPv6, TCP/IP performs IP filtering for these packets and denies these packets by default. You must consider these packets when configuring filter rules for IPv6. For example, if you configure permit rules for IPv6 TCP or UDP traffic over an OSA-Express QDIO interface, but do not configure permit rules for the neighbor discovery address resolution flows over the interface, the traffic will not succeed because the stack denies the ICMPv6 neighbor solicitation and neighbor advertisement packets during address resolution. Also, you must configure permit filter rules for neighbor solicitation and neighbor advertisement packets, so that the stack can perform duplicate address detection (and learn about valid duplicate addresses).
In addition, for the stack to be able to learn about neighbors, you must configure permit filter rules for outbound router solicitations and inbound router advertisements. Similarly, for the stack to be able to perform the MLD listener function, you must configure permit filter rules for outbound MLD listener reports and inbound MLD listener query packets.

For example filter rules to permit neighbor discovery and MLD packets, see the TCP/IP sample profile and policy sample.

**Guideline:** Configure permit rules for neighbor discovery and MLD packets.

**Result:** z/OS Communications Server does not apply IPSec protection for outbound neighbor discovery or MLD packets, but does apply permit and deny actions for these packets. If such an outbound packet matches an IP filter rule that specifies an IPsec action, the stack permits the packet but does not encapsulate it.

**Stateless address autoconfiguration**

If you use autoconfiguration, your IPv6 addresses might not be predictable. To configure IP filter rules for dynamic Security Associations with autoconfigured IPv6 addresses, you need to specify the IP addresses using wildcards.

Manual Security Associations typically use specific IP addresses for the endpoints. You can use wildcards for the security endpoint addresses so that the data endpoints and security endpoints are considered identical. Alternatively, you can use predictable IPv6 addresses for the security endpoints. You can obtain predictable IPv6 addresses by configuring full 128-bit IPv6 addresses on your INTERFACE statements, by specifying the INTFID keyword on your INTERFACE statements, or by using VIPAs.

**IPv6-specific protocols**

The protocol number for ICMPv6 (58) is different from the protocol number for IPv4 ICMP (1); remember this when configuring IPv6 filter rules.

The handling of fragments in IPv6 is different from IPv4. For information about fragmented IPv6 packets, see “Routed traffic and fragmented packets” on page 869.

**IPv6 address types**

You can configure IP filter rules for any valid IPv6 address, including multicast addresses, link-local addresses, IPv4-mapped addresses, and so on.

You can configure IPSec tunnels for link-local and global addresses. For multicast addresses, you can configure manual tunnels but not dynamic tunnels. You cannot configure IPSec tunnels for IPv4-mapped addresses.

**IPv6 extension headers**

If an IPv6 packet contains an extension header that is a type 0 or type 2 routing header, the stack performs IP filtering using the final destination address of the packet based on the routing header contents, rather than using the destination address in the IP header.

**Considerations for IPv6 OSPF security**

IPv4 OSPF authentication is implemented within the IPv4 OSPF protocol. However, IPv6 OSPF security (both authentication and encryption) is implemented by using IPSec. Because OSPF uses both multicast messages and unicast messages, it is not possible to use dynamic tunnels for OSPF traffic. Instead, manual tunnels must be used. The IBM Configuration Assistant for z/OS Communications Server automates the process of creating IPv6 OSPF tunnels. The following information describes the process of manually creating the IPv6 OSPF tunnel definitions.

It is expected that the same manual tunnel is to be used for all link-local unicast and multicast traffic. Additional tunnels might be used for IPv6 OSPF virtual links.
Because multicast traffic is one-to-many, the manual tunnel must use the same Security Parameter Index (SPI) and keys for inbound and outbound traffic. Whatever SPI values and keys are used must be coordinated with all IPv6 OSPF peers on the LAN segment. Also, because this manual tunnel is to be used to protect traffic with various source and destination addresses, you must specify any6 for the local and remote security endpoint locations. The following example uses AH authentication using the SHA algorithm, and ESP encryption using the DES algorithm.

```plaintext
IpManVpnAction tunnel-ipv6ospf-internal
{
  LocalSecurityEndpointAddr   any6
  RemoteSecurityEndpointAddr  any6
  AuthOutboundSa              2700 0xa66e1b72e58a367ed39d62daef84d5d9222cfe1
  AuthInboundSa               2700 0xa66e1b72e58a367ed39d62daef84d5d9222cfe1
  HowToAuth                   AH HMAC_SHA1
  HowToEncrypt                DES
  EncryptOutboundSa           2701 0x3e6dcf72459ef551
  EncryptInboundSa            2701 0x3e6dcf72459ef551
  HowToEncap                  transport
}
```

For the filter rules, you first need to create an IP service to describe the OSPF traffic. To distinguish the traffic, you specify the OSPF protocol, and the SECCLASS of the interfaces on which the traffic will flow. For the purpose of this example, assume that the interfaces for the LAN segment that is being protected are defined with SECCLASS 10.

```plaintext
IpService service-ipv6ospf-internal
{
  Protocol               ospf
  Direction              bidirectional
  Routing                local
  SecurityClass          10
}
```

You now need to define three filter rules to match the OSPF traffic. The first filter rule matches all link-local unicast traffic on the LAN segment:

```plaintext
IpFilterRule ipv6ospf-unicast-internal
{
  IpSourceAddr               fe80::/10
  IpDestAddr                  fe80::/10
  IpServiceRef                service-ipv6ospf-internal
  IpGenericFilterActionRef    ipsec-nolog
  IpManVpnActionRef           tunnel-ipv6ospf-internal
}
```

The remaining two filter rules are for the OSPF link-local multicast traffic. The first rule matches outbound multicast traffic, which has a link-local unicast source address and a link-local multicast destination address. The second rule matches inbound multicast traffic, which has a remote (destination) address that is link-local unicast, and a local (source) address that is link-local multicast. These rules are as follows:

```plaintext
IpFilterRule ipv6ospf-outbound-multicast-internal
{
  IpSourceAddr               fe80::/10
  IpDestAddr                  ff02::/16
  IpServiceRef                service-ipv6ospf-internal
  IpGenericFilterActionRef    ipsec-nolog
  IpManVpnActionRef           tunnel-ipv6ospf-internal
}
IpFilterRule ipv6ospf-inbound-multicast-internal
{
  IpSourceAddr               ff02::/16
  IpDestAddr                  fe80::/10
  IpServiceRef                service-ipv6ospf-internal
  IpGenericFilterActionRef    ipsec-nolog
  IpManVpnActionRef           tunnel-ipv6ospf-internal
}
```
Virtual links

You can also configure IPsec protection for IPv6 OSPF virtual links. You can use the following method to configure manual tunnels for IPv6 OSPF virtual links.

Guideline: Because virtual links use global unicast addresses, you should use dynamic tunnels for IPv6 OSPF virtual links whenever possible. Dynamic tunnels provide numerous benefits over manual tunnels.

Because the virtual link addresses are not known beforehand, you must specify the security endpoint addresses for the manual tunnel with a wildcard value. The Security Association does not protect multicast traffic, so the inbound and outbound SPI values and keys do not need to be identical. Whatever SPI values and keys you use must be coordinated with the virtual link peer.

```
IpManVpnAction tunnel-ipv6ospfvirt-internal
{
  LocalSecurityEndpointAddr  any6
  RemoteSecurityEndpointAddr any6
  AH HMAC_SHA1
  AuthOutboundSa  2702 0xf5c58a6e6f0761b68f424f39257f0ea89a4be3b4
  AuthInboundSa   2703 0x39a341ed1b7127b7905df2411ed0770854b54d10
  HowToEncrypt DES
  EncryptOutboundSa 2704 0xb9571d29fe98ecca
  EncryptInboundSa 2705 0xef24a0c011e7f3b0ed
  HowToEncap transport
}
```

Only one filter rule is needed for the virtual link. For this example, the same IP service used for the link-local traffic is used, which restricts this filter rule to OSPF traffic flowing over interfaces with SECCLASS 10. Because the virtual link addresses are not known beforehand, the filter rule addresses are specified with a wildcard value to include all global unicast addresses. If you have more specific information about the address prefixes for the virtual link endpoints, you can use this to further restrict the addresses on the filter rule.

```
IpFilterRule ipv6ospf-virtual-internal
{
  IpSourceAddr              4000::/3
  IpDestAddr                4000::/3
  IpServiceRef             service-ipv6ospf-internal
  IpGenericFilterActionRef ipsec-nolog
  IpManVpnActionRef        tunnel-ipv6ospfvirt-internal
}
```

Default IP filter policy and IP security policy

Policy Agent provides IP filter policy to the stack, as defined by the IP security policy configuration files. For the stack to be enabled for IP security for IPv4, the TCP/IP profile must have IPCONFIG IPSECURITY coded. For the stack to be enabled for IP security for IPv6, the TCP/IP profile must also have IPCONFIG6 IPSECURITY coded. For the stack to receive configured policy, the Policy Agent must be active. IP filter policy is installed when Policy Agent and the stack are active. If Policy Agent is not active when an IPSECURITY-enabled stack initializes, the stack cannot be provided with IP filter rules from that policy. Therefore, in the interest of network security, the stack provides a default IP filter policy when an IP filter policy is unavailable from Policy Agent. The default IP filter policy effectively denies all network traffic, with the exception of some select ICMP and ICMPv6 messages that are necessary for internal stack function. These deny rules are not explicitly coded, but rather are always implicitly added at any time that the default IP filter policy is in effect. The default IP filter policy can be in effect at times other than stack initialization. Default IP filter policy is in effect in all of the following cases:

- An IPSECURITY-enabled TCP/IP stack has been started but Policy Agent has not been started, or an IPSECURITY-enabled TCP/IP stack has been started but Policy Agent has not completely initialized.
- An IPSECURITY-enabled TCP/IP stack and Policy Agent have been started, but no IP security configuration file exists.
- An IPSECURITY-enabled TCP/IP stack and Policy Agent have been started, but the IP security configuration file contains errors.
• An IPSECURITY-enabled TCP/IP stack and Policy Agent have been started, but no IpFilterPolicy statement exists in either IP security configuration file.

• An IPSECURITY-enabled TCP/IP stack and Policy Agent have been started, and IP filter policy has been provided to the stack, but the stack is using the default IP filter policy because the `ipsec -f default` command was issued.

This default behavior ensures that network security is not compromised in the event that IP filter policy is not installed, and is consistent with a secure default-deny policy. However, you can modify the default IP filter policy by coding an IPSECRULE statement (for IPv4) or IPSEC6RULE statement (for IPv6) in the TCP/IP profile. The IPSECRULE and IPSEC6RULE statements describe the attributes of the IP traffic that is allowed when the default policy is active. Because the default behavior is to deny all network traffic, IPSECRULE and IPSEC6RULE statements are always permit rules that denote exceptions to the default-deny policy.

It is also important to note that neither the default IP filter policy nor a modified default IP filter policy provides authentication and encryption capabilities such as those provided by a complete IP security policy; it offers the stack only the ability to perform simple IP filtering in the absence of an IP security policy.

Modifying the default IP filter policy

The default IP filter policy is in effect when the IP security policy, as configured in the Policy Agent, is not available. The default IP filter policy denies all network traffic, unless you modify the TCP/IP profile.

Two IP filters are created by the default IP filter policy, one denying IPv4 inbound traffic and the other denying IPv4 outbound traffic. If IP security for IPv6 is also enabled, the stack also creates two similar filters, one denying IPv6 inbound traffic and the other denying IPv6 outbound traffic. For example, assuming that the default IP filter policy is active, the following sample of the `ipsec -f display` command shows that SYSDEFAULTDENYRULE was added to the filter table:

```
ipsec -f display

***********************************************************************
Use IPSECRULE and IPSEC6RULE for permit rules that denote exceptions to the default-deny policy. When the default IP filter policy is active, these permit rules appear in the default IP filter table before the SYSDEFAULTDENYRULE entries. Typically, these exceptions are few and are used for administrative access to the system when IP security policy is unavailable. For instance, a sample default set of permit rules might include entries to provide the following access:

- Administrative access
- Basic network services, such as DNS and OSPF routing advertisements
- Use of ping to test for server availability

IPSECRULE and IPSEC6RULE entries are coded in the IPSEC block of the TCP/IP profile. They describe the attributes of the IP traffic that is allowed when the default IP filter policy is active. These rules can specify criteria such as source address, destination address, protocol, source port, destination port, routing, direction, and security class.

IPSECRULE and IPSEC6RULE entries always have an action of permit; there is no action specification for deny or permit with IPsec protection.

Assuming the administrative machine has an IP address of 9.1.1.2 and connects through an interface whose security class is 100, the following sample IPSECRULE entries enable the z/OS system to communicate IPv4 DNS queries and OSPF routing advertisements to anyone, while giving blanket access to the administrator. The example IPSEC6RULE entry permits any ICMPv6 packets. An asterisk (*) is the default and represents all, indicating that any packet matches this attribute.

</tr>
</tbody>
</table>

Any IPSECRULE and IPSEC6RULE entries that are coded are given a system-generated name for purposes of display. These rules are prefixed with the string SYSDEFAULTRULE. The IPSECRULE entries that are configured in the previous example are reflected in the `ipsec -f display` command as shown in the following example. Two rules are created for each IPSECRULE or IPSEC6RULE entry configured, one for each direction. By default, IPSECRULE and IPSEC6RULE entries define bidirectional filters. If you want to limit the filter to inbound or outbound traffic, use the DIRECTION parameter to specify direction of the traffic to be filtered. Because the five rules that are configured in the example IPSEC block are bidirectional, they have been expanded into 10 IP filters. Four additional filters have been created for the default-deny behavior. Each rule is given a unique filter name comprised of SYSDEFAULTRULE.number, where number is a numerical extension that indicates the relative order of the rule in the IP filter table. Because each bidirectional IPSECRULE and IPSEC6RULE statement results in multiple filter rules with the same name (inbound and outbound), a FilterNameExtension value is assigned by the system to uniquely identify each filter.

```
ipsec -f display

For an IP security-enabled stack, one of the two security policies is always in effect, either the default policy or the IP security policy as defined in Policy Agent. The policy that is in effect at any given time is considered to be the active policy. The source field of the report header for the `ipsec -f display` command can be used to determine which policy is currently active as follows:

```
ipsec -f display
CS V1R12 ipsec Stack Name: TCPCS Tue Feb 16 09:55:31 2010
Primary: Filter Function: Display Format: Detail
Source: Stack Profile Scope: Current TotAvail: 14
Logging: On Predecap: Off DVIPSec: No
NatKeepAlive: 0 FIPS140: No
Defensive Mode: Inactive
FilterName: SYSDEFAULTRULE.1
FilterNameExtension: 1
```

Stack Profile indicates that the default IP filter policy is active; Stack Policy would indicate that the IP security policy as defined in Policy Agent is active.

You can also choose which policy is the active policy. The `ipsec` command provides the ability to switch the active policy between the default IP filter policy in the TCP/IP profile and the IP security policy in Policy Agent. Issuing the `ipsec -f default` command causes the default policy to become the active policy, while issuing the `ipsec -f reload` command reloads the IP security policy from Policy Agent, provided that Policy Agent is active and that IP security has been correctly configured.

There are cases in which you might want to switch to the default policy. For instance, in the event of a security breach, the `ipsec -f default` command allows only the network traffic that has been explicitly coded in the TCP/IP profile IPSEC block, which typically permits only administrative access.

It is important to use the `ipsec -f default` command with discretion. Issuing `ipsec -f default` on an operational system can have a dramatic impact and cause packets to be dropped, depending on how the IPSECRULE and IPSEC6RULE entries are coded. Consider the use of `ipsec -f default` as equivalent to a shutdown, and do not use it in normal circumstances unless the following conditions are true:
The system is in maintenance mode.
There is no productive work being done on the system.
The site policy for IP traffic is default-allow and the appropriate IPSECRULE and IPSEC6RULE entries were coded.

Malicious use of network resources can be identified by unusual IP traffic conditions, console messages, or log inspection. Should a security concern arise in a production environment, the following steps should be performed quickly to minimize the impact of potentially restricted flow of IP traffic.

1. To secure the system, switch to the default IP filter policy by issuing the `ipsec -f default` command.
2. Analyze system logs to determine the nature and the source of the security concern. If packet logging was active for the time period in question, then inspect the TRMD packet filtering log entries.
3. Update the IP security policy configuration to alleviate the security concern. For example, add an IpFilterRule that denies any suspicious IP address or port use, and activate IP filter logging.
4. Activate the updated IP security policy from the Policy Agent by issuing the `ipsec -f reload` command.
5. Verify that the security concern is eliminated. Monitor the network traffic and inspect the system logs, including any related IP filter log messages.

### IP filter logging

Monitoring network events is an important aspect of network security. Logs can be used to verify that policies have been correctly configured and enforced, or to gather statistics on any traffic of interest. For instance, traffic that is persistently denied might be suspect. With IP filter logging, you can inspect any traffic on the system and even fine tune the configuration to show only those entries of interest. Logging can be controlled at the global level or at the individual rule level, including the ability to specify whether to log permitted traffic, denied traffic, or both. The IP filter log entries provide detailed information about each packet, including the rule that the packet matched and any pertinent IPSec information.

TRMD and syslogd provide the logging service for IP security. If running in the common INET environment, you must configure one instance of TRMD for each stack on a z/OS system.

**Guideline:** Exhaustive logging of IP traffic can have a negative effect on performance. If logging is excessive, it can be turned off temporarily at the global level while the appropriate logging modifications are made to the individual IP filter rules. IP filter logging is controlled by the IpFilterLogging parameter on the IpGenericFilterAction statement. For more details, see `z/OS Communications Server: IP Configuration Reference`.

### IP filter discard action

When packets are denied by IP filter policy, IP security supports sending an ICMP or ICMPv6 destination unreachable message, which indicates that a packet is administratively prohibited. You can enable this action for the implicit Policy Agent deny filter rules using the ImplicitDiscardAction parameter on the IpFilterPolicy statement, and for individual filter rules using the DiscardAction parameter on the IpGenericFilterAction statement.

**Rule:** To make a system effectively invisible to attackers, choose the discard action Silent. Choose the discard action ICMP only in cases in which doing so is a useful diagnostic aid, such as for users of internal networks.
Data encryption and authentication - IPSec

To participate in a virtual private network (VPN), a host must encrypt and authenticate individual IP packets between itself and another communicating host. IPSec is one of several mechanisms for achieving this, and one of the more versatile.

IPSec is defined by the IPSec working group of the IETF. It provides authentication, integrity, and data privacy between any two IP entities. Management of cryptographic keys and Security Associations can be either manual or dynamic using an IETF-defined key management protocol called Internet Key Exchange (IKE).

IPSec provides flexible building blocks that can support a variety of configurations. Because an IPSec Security Association can exist between any two IP entities, it can protect a segment of the path or the entire path. The main advantage of using IPSec for data encryption and authentication is that IPSec is implemented at the IP layer. Consequently, any network traffic that is carried by an IP network is eligible to use IPSec services without any special changes to higher level protocols that are used by applications. However, if the system is using any of these alternate security protocols to secure specific applications, IP filtering can be used to avoid the overhead of multiple security protocols. For example, you might want to exclude web traffic (based on the well-known secure port of the web server, port 443) from IPSec coverage because you would like to use SSL.

IPSec enables the creation of VPNs. A VPN enables an enterprise to extend its network across a public network, such as the Internet, through a secure tunnel using Security Associations. IPSec VPNs enable the secure transfer of data over the public Internet for same-business and business-to-business communications, and protect sensitive data within an enterprise’s internal network.

IPSec uses IP filtering to determine which traffic should be protected by IPSec. A special type of filter action specifies to permit the traffic, but only with IPSec protection. The IP filters represent IP security policy to the stack by specifying the traffic that requires IPSec protection. The filters are also used in locating the outbound IPSec Security Association, and for verifying that inbound traffic is received using the correct Security Association.

The IETF has standardized the IPSec protocol suite and key management schemes in a series of IPSec RFCs. For more information on these RFCs, see Appendix G, “Related protocol specifications,” on page 1381.

IPSec has three major components:

• IP Authentication Header (AH)
• IP Encapsulating Security Payload (ESP)
• Internet Key Exchange (IKE)

AH and ESP protocols

IPSec uses two distinct protocols, Authentication Header (AH) and Encapsulating Security Payload (ESP), which are defined by the IETF.

The AH protocol provides a mechanism for authentication only. AH provides data integrity, data origin authentication, and an optional replay protection service. Data integrity is ensured by using a message digest that is generated by an algorithm such as HMAC-MD5 or HMAC-SHA. Data origin authentication is ensured by using a shared secret key to create the message digest. Replay protection is provided by using a sequence number field with the AH header. AH authenticates IP headers and their payloads, with the exception of certain header fields that can be legitimately changed in transit, such as the Time To Live (TTL) field.

The ESP protocol provides data confidentiality (encryption) and authentication (data integrity, data origin authentication, and replay protection). ESP can be used with confidentiality only, authentication only, or both confidentiality and authentication. When ESP provides authentication functions, it uses the same algorithms as AH, but the coverage is different. AH-style authentication authenticates the entire IP packet, including the outer IP header, while the ESP authentication mechanism authenticates only the IP datagram portion of the IP packet.
Either protocol can be used alone to protect an IP packet, or both protocols can be applied together to the same IP packet. The choice of IPSec protocol is determined by the security needs of your installation, and is configured by the administrator. It does not have to be applied system-wide, and can be configured differently for each set of connection endpoints. For a dynamic tunnel, the choice of IPSec protocol is configured using the IpDataOffer statement in an IP security policy configuration file. For a manual tunnel, the choice of IPSec protocol is configured using the IpManVpnAction statement in an IP security policy configuration file. For more details about the IpDataOffer statement and the IpManVpnAction statement, see z/OS Communications Server: IP Configuration Reference.

z/OS IP security requires authentication due to potential security exposures when encryption is used alone. Authentication can be provided by the ESP or AH protocol. The complete list of combinations for authentication and encryption that are provided by z/OS IP security and that can be used for a specific connection are shown in Table 49 on page 893.

**Guideline:** RFC 4835 discourages the use of DES. Use the AES encryption algorithms wherever possible for better security and interoperability.

**Restriction:** The combination of ESP protocol for encryption and AH protocol for authentication is not supported by IKEv2. If you are using IKEv2 and require both encryption and authentication, you should use ESP for both.

**Encapsulation**

In the process of applying either AH or ESP to an IP packet, the original IP packet is modified. Outbound packets are rebuilt with additional IPSec headers in a process known as encapsulation, while inbound
packets are stripped of their IPSec headers in a process known as decapsulation. Before leaving a host, outbound packets are encapsulated using a cryptographic key that is known to both communicating hosts. Inbound packets are decapsulated on the receiving side using the same cryptographic key, thereby recovering the original datagram. If encryption is used, any packet that is intercepted on the IP network is unreadable to anyone without the encryption key. Any modifications to the IP packet while in transit are detected by authentication processing at the receiving host and discarded.

**Transport mode and tunnel mode**

The manner in which the original IP packet is modified depends on the encapsulation mode used. There are two encapsulation modes used by AH and ESP, transport and tunnel.

Transport mode encapsulation retains the original IP header. Therefore, when transport mode is used, the IP header reflects the original source and destination of the packet. Transport is most often used in a host-to-host scenario, where the data endpoints and the security endpoints are the same. A transport mode encapsulated datagram is routed, or transported, in the same manner as the original packet.

**Figure 105 on page 894** shows an IPv4 packet that is encapsulated using AH in transport mode:

**Figure 107. IPv6 packet encapsulated using AH in transport mode**

For a description of the IPv6 mutable fields, see RFC 2402. For information about accessing RFCs, see Appendix G, “Related protocol specifications,” on page 1381.

**Figure 108 on page 895** shows an IPv6 packet that is encapsulated using ESP in transport mode:

![IPv6 packet encapsulated using ESP in transport mode](image)
Figure 108. IPv6 packet encapsulated using ESP in transport mode

Tunnel mode encapsulation builds a new IP header containing the source and destination address of the security endpoints. When tunnel mode is used, the outer IP header reflects the source and destination of the security endpoints, which might or might not be the same as the original source and destination IP address of the data connection. The choice of transport or tunnel mode depends on the structure of the network and relies heavily on logical connections between the endpoints. Tunnel mode is required if one of the IKE peers is a security gateway that is applying IPSec on behalf of another host or hosts. A datagram that is encapsulated in tunnel mode is routed, or tunneled, through the security gateways, with the possibility that the secure IPSec packet will not flow through the same network path as the original datagram. To successfully encapsulate and send an outbound packet, the route table must contain a route that can be used to reach the security gateway, as well as a route that can be used to reach the data endpoint. If policy-based routing is being used on a TCP/IP stack where IP security is active, it is important to understand how the two functions interact. For more information, see “Considerations for using policy-based routing with IP security” on page 341.

Authenticated

Figure 112. IPv6 packet encapsulated using ESP in tunnel mode

Do not confuse tunnel mode encapsulation with IKE tunnel or IPSec tunnel. In this context, tunnel refers only to the method by which IPSec packets are constructed, while IKE and IPSec tunnels are conceptually defined as secure logical connections between hosts. IPSec tunnels can use transport mode or tunnel mode encapsulation.

For a dynamic tunnel, the choice of encapsulation mode is configured using the IpDataOffer statement in an IP security policy configuration file. For a manual tunnel, the choice of IPSec protocol is configured using the IpManVpnAction statement in an IP security policy configuration file. For more details about the IpDataOffer statement and the IpManVpnAction statement, see z/OS Communications Server: IP Configuration Reference.

Guideline: In host-to-host scenarios, transport mode is commonly used because it does not incur the overhead of having to build an additional IP header. However, tunnel mode is equally valid.

Tip: Any configurations that include a secure gateway as an IKE endpoint require tunnel mode; however, if IKEv2 is used, then the selection of encapsulation mode is performed automatically. The IKED will use transport mode if it determines that the connection is host-to-host; otherwise the IKED will use tunnel mode encapsulation. This behavior can be overridden by using the HowToEncapIKEv2 parameter on the associated KeyExchangeAction statement; see the KeyExchangeAction statement in z/OS Communications Server: IP Configuration Reference for details.

Rule: If you are using Sysplex-Wide Security Associations, a dynamic Security Association cannot use a subnet or range that encompasses a DVIPA address. For takeover to work consistently, Security Associations must be negotiated for single IP addresses only. If two DVIPAs that are covered by the same Security Association are subsequently taken over by two different backup stacks, the coverage of the Security Association is ambiguous because it is then linked to two DVIPAs on two different stacks.

UDP encapsulation of IPSec ESP packets

When building an ESP packet, it can be further encapsulated by placing a UDP header in front of the ESP header. This is known as UDP encapsulation. UDP encapsulation is used to allow IPSec traffic to successfully traverse a NAT device. For more information on NAT traversal (NATT), see “IPSec and network address translation devices” on page 904. z/OS Communications Server supports NAT traversal for IPv4 traffic only.

z/OS Communications Server supports both tunnel and transport modes of UDP encapsulation.

As shown in Figure 113 on page 897, UDP-encapsulated transport mode inserts a UDP header in between the IP header and the ESP header of a normal transport mode ESP packet.

896 z/OS Communications Server: IP Configuration Guide
As shown in Figure 114 on page 897, UDP-encapsulated tunnel mode inserts a UDP header in between the new IP header and the ESP header of a normal tunnel mode ESP packet.

Figure 114. UDP-encapsulated tunnel mode

When an IPSec UDP-encapsulated packet is built, the source and destination port values in the UDP header are set to the IKE port value of 4500.

Configure the choice of transport or tunnel mode using the IpDataOffer statement in the IP security policy configuration file. For more details about the IpDataOffer statement, see z/OS Communications Server: IP Configuration Reference.

The decision to use a UDP-encapsulated mode is not configured, but instead inferred, when a NAT is detected between two IKE daemons.

**IPSec and symmetric key management**

At the center of encryption and authentication is the notion of a cryptographic key. Security endpoints use keys to encrypt and decrypt data. The IPSec protocols create Security Association keys that are directional. As shown in Figure 115 on page 897, the key that is used to encrypt outbound data on one host is used to decrypt the same data on the remote host, while the key that is used to encrypt data on the remote host is used to decrypt data on the local host.

Figure 115. Symmetric encryption

This type of encryption is known as symmetric, because it requires that both hosts use the same keys on the same data.
Manual key management

IPSec keys and values can be configured manually. Manual management of keys was the only non-proprietary option for implementing IPSec before the standardization of the IKE protocols. In a manual IPSec configuration, the keys that are used to encrypt data, and the Security Parameter Index (SPI) values that are used to uniquely identify a Security Association, are determined by the administrator and configured beforehand on both hosts. However, the steps that you must take to manually generate encryption keys can become quite cumbersome, as shown in the following examples:

- A single IPSec connection requires two keys, because encryption keys are unidirectional (one for inbound traffic, one for outbound traffic).
- A single IPSec connection can require up to four SPI values, depending on the type of IPSec protection required.
- The keys and SPI values must be individually installed on both the local and remote system.
- To help ensure that the keys are not compromised, they need to be changed periodically and updated on both hosts. Manual IPSec has no key refresh capabilities unless the Security Associations are deactivated, reconfigured with the new key, and then reactivated.
- During the refresh maintenance period, IPSec functionality is unavailable, disrupting any IP traffic requiring IPSec protection.
- Because of the disruptive nature of key refresh with manual IPSec, key lifetimes are frequently defined with much larger values, thus increasing the security exposure.
- These steps must be carried out for each remote host that communicates with IPSec, with different keys for each of them.

In a small installation with minimal security concerns, this manual process can work quite well, and might actually be preferable. However, given the large number of communicating hosts in a typical network, this manual process quickly becomes unwieldy, error prone, maintenance intensive, and not scalable.

Nevertheless, z/OS IP security does support manual IPSec configuration for compatibility with systems that use it. If an IP filter rule specifies a manual ipsec action, the corresponding action is consulted to determine all aspects of the encryption and authentication policy for that data, including the identities of the communicating hosts, the keys that are used for encryption and authentication of outbound and inbound packets, and the SPI values. Manual IPSec protection is configured using the IpManVpnAction statement in an IP security policy configuration file. For more details about the IpManVpnAction statement, see z/OS Communications Server: IP Configuration Reference.

Dynamic key management - IKE and IPSec negotiations

The primary role of the IKE daemon in an IP security environment is the automatic management of cryptographic keys. Dynamic key management, as provided by the IKE daemon, removes much of the administrative burden that is associated with the creation, distribution, and maintenance of cryptographic keys. IKE provides the following services:

- Host authentication (ensuring that both hosts are certain of the other's identity)
- The negotiation of a Security Association as follows:
  - Agreeing on the type of traffic to be protected
  - Agreeing on the authentication and encryption algorithms to be used
  - Generating cryptographic keys
- Nondisruptive periodic refresh of keys
- The deletion of Security Associations whose lifetimes have expired

There are two versions of the IKE protocol: IKEv1 and IKEv2. The architectural differences between IKEv1 and IKEv2 are as follows:

- IKEv2 requires fewer network flows for Security Association establishment.
- IKEv2 provides a mechanism for re-keying an IKE Security Association without reauthentication, which reduces the CPU cost.
**IKEv2** allows each peer to manage its own values for lifetime and lifescape, whereas in IKEv1 Security Association lifetimes and lifescapes are negotiable attributes. This reduces coordination of configuration parameters between the peer nodes and avoids potential race conditions when the SAs expire.

**IKEv2** supports the hash and URL certificate encoding types, but IKEv1 does not.

The following difference between IKEv1 and IKEv2 is specific to the z/OS implementation:

- To use any authentication method for IKEv2 based on a digital signature, the certificate service must be provided by an NSS server. You cannot use the IKED native certificate service.

IKE operates at the application layer. IKE negotiations are communicated between two IKE peers by a series of UDP messages. Ports 500 and 4500 are used by the IKE daemon. For both IKEv1 and IKEv2, Security Association negotiation proceeds in phases. In each phase, IKE negotiates a Security Association with a remote host. During the initial phase, IKE negotiates a phase 1 Security Association, which establishes a secure channel over which the IKE peers communicate. The phase 2 Security Association is negotiated to provide data authentication and encryption for subsequent IP traffic. The distinction between a phase 1 Security Association and a phase 2 Security Association is what the Security Associations protect:

- **Phase 1 Security Associations** are used to protect IKE messages that are exchanged between two IKE peers, or security endpoints.
- **Phase 2 Security Associations** are used to protect IP traffic, as specified by the security policy for a specific type of traffic, between two data endpoints.

Every Security Association that the IKE daemon negotiates contains information about the type of traffic it is to protect, the IP addresses of the two endpoints, the type of encryption or authentication that is provided, the keys that are used to protect data, how often the keys are refreshed, and an identifier called a Security Parameter Index (SPI) that is used to uniquely identify the Security Association.

An IPSec configuration contains separate policies governing each phase. Although many of the same attributes apply for phase 1 and phase 2 negotiations and keys, there are two major differences:

- **The phase 1 Security Association can specify only a single IP address for the security endpoints**, while the **phase 2 Security Association can specify a contiguous range or subnet as the data endpoint**.
- **The phase 1 Security Association must specify an encryption method**, while encryption is optional for the **phase 2 Security Association**. An authentication method must be specified for both the phase 1 and phase 2 Security Association.

The exact specifications for each phase 1 Security Association and each phase 2 Security Association are configured in the IP security configuration file. The specific IP security policy statements that apply to the phase 1 and phase 2 specifications are the KeyExchangeOffer statement (phase 1) and the IpDataOffer statement (phase 2). For more details about the KeyExchangeOffer statement and the IpDataOffer statement, see z/OS Communications Server: IP Configuration Reference.

Because the IKE protocols deal with initializing keys, they must be capable of running over links where no security is assumed to exist. IKE addresses the problem of secure key distribution by automatically deriving the keying material using a Diffie-Hellman exchange during the IKE phase 1 negotiation. This automatic creation and distribution of the key during phase 1 eliminates the need to manually distribute the session key between remote sites. Besides the obvious administrative advantage of IKE, the manual method of key distribution is prone to key compromise.

In addition, IKE non-disruptively refreshes the session keys based on the security policy of the installation. IKE specifies that this can be based on time (lifetime) and bytes transmitted (life size). IKE provides a property called perfect forward secrecy (PFS), and if PFS is used, each phase 2 key is derived independently through a separate Diffie-Hellman exchange. With PFS, if a single key is compromised, the integrity of subsequently generated keys is not affected.

**Phase 1**

Before IKE can negotiate the security parameters and generate the keys that are used to protect data between the two hosts, it must have a way of protecting the negotiation itself. The **IKE phase 1 negotiation** provides this protection by performing two tasks:
• Authenticating the IKE peer

Peer authentication is performed either by the pre-shared key method or a digital signature method. For details of peer authentication, see “Peer authentication” on page 900.

• Generating cryptographic keys

A Diffie-Hellman exchange is performed to create a shared secret between the two IKE peers. This shared secret is then used in the generation of keying material. Keys to encrypt and authenticate messages sent during phase 2 are produced from this keying material. Cryptographic keys used by phase 2 Security Associations are generated from this keying material. The creation of the Diffie-Hellman shared secret is secure, but computationally expensive.

The phase 1 Security Association contains the following information:

• The key that is used to encrypt IKE messages
• The key that is used to authenticate IKE messages
• Keying material used to generate keys produced during phase 2
• The security endpoints (single IP addresses)
• The type of protection that is required (authentication and encryption)
• How often the keys should be renewed
• A Security Parameter Index (SPI) value, which is used together with the remote security endpoint IP address to uniquely identify the Security Association
• The Diffie-Hellman group, which is an attribute of the public key cryptography algorithm

Because the tasks of authentication and master key generation are so resource intensive, a phase 1 Security Association is usually refreshed less often than a phase 2 Security Association.

Peer authentication

Peer authentication is a critical part of a phase 1 negotiation. Before two hosts can participate in the negotiation of a Security Association, each must be authorized to negotiate with the other. IKE does not allow negotiation with a host that cannot be properly identified. IP addresses are not a guarantee of identity (an IP packet can be spoofed), and the IP address from an inbound packet alone is insufficient to prove the identity of a remote host. Therefore, the IKE daemon needs a more reliable method for determining the remote host’s identity. This proof of identity is first presented during the phase 1 negotiation.

z/OS IP security implements two methods of host authentication as follows:

• Digital signature (RSA or ECDSA)
• Pre-shared key

Each of these authentication methods provides a way for hosts to verify the identity of the other, and while the pre-shared key mechanism is easier to configure, the digital signature methods are more versatile, secure, and scalable. The choice of authentication method is configured in an IP security policy configuration file for each IPSec connection, using the KeyExchangeOffer statement for IKEv1 and the KeyExchangeAction statement for IKEv2. For more details about the KeyExchangeOffer and KeyExchangeAction statements, see z/OS Communications Server: IP Configuration Reference.

Peer authentication is not the same as data authentication. Data authentication uses IPSec to authenticate an IP packet after an IPSec Security Association has been negotiated by two IKE daemons. Peer authentication is used during an IKE phase 1 negotiation to identify two IKE peers to each other before the establishment of any phase 2 Security Associations.

Guideline: As a matter of security, pre-shared keys should not be shared among multiple remote IKE peers. If the pre-shared key method of authentication is used, each remote host should have its own unique key and KeyExchangeRule specific to that host. If multiple remote hosts are identified by the same KeyExchangeRule, digital signature methods of peer authentication should be used.
Rule: For IKEv2, if digital signatures are used as the authentication method, then the IKED must be configured to use the certificate services of the NSSD. For more details about the configuring the IKED and the NSS IPSec client, see Chapter 18, “Network security services,” on page 1055.

Identity information

Multiple identities can be assigned down to the level of individual IP addresses for each IKE negotiation, or for ease of configuration, a single identity can be assigned to represent the IKE daemon for the TCP/IP stack. With either method, the identity that is assigned must be an identity that is known to the remote IKE peer. Similarly, the local server must know the identity of any remote IKE peer with which it is to negotiate.

Guideline: Do not use the same identity on more than one TCP/IP stack or z/OS system image. IKED assumes that an identity is not used by any other stack, and this assumption can lead to a disruption of IPSec service for other stacks when identities are shared between stacks.

The identity can be one of the following types:

- X500dn (the host’s X.500 distinguished name)
- IpAddr (an IP address)
- Fqdn (a fully qualified domain name)
- UserAtFqdn (an email address)
- KeyID (EBCDIC, ASCII or hexadecimal string)

Restriction: An identity of KeyID is valid only when using preshared key authentication.

If a digital signature method of peer authentication is used, the local identity must be in an X.509 digital certificate on the IKE daemon’s key ring for an IKEv1 negotiation, or on the NSS server’s key ring for an IKEv1 or IKEv2 negotiation that uses the NSS certificate service. If the pre-shared key method of peer authentication is used, any of the identity types can be used to identify this IKE peer. Because digital certificates are not used in the pre-shared key method, the only requirement for the use of an identity type is that it be known to both hosts.

Identity information is configured using the LocalSecurityEndpoint and RemoteSecurityEndpoint statements in an IP security policy configuration file. For more details about the LocalSecurityEndpoint and RemoteSecurityEndpoint statements, see z/OS Communications Server: IP Configuration Reference.

Digital signatures

Digital signature authentication methods include RSA and ECDSA. They use X.509 digital certificates. An X.509 digital certificate contains information that was verified by a certificate authority to uniquely identify a host. IKE peers exchange certificates during the phase 1 negotiation to identify each other. Of the information that is typically included in an X.509 digital certificate, there are four fields that are relevant to an IKE exchange:

Subject Name

A certificate's subject name is the unique name by which the host is known. The subject name is used to extract the host’s X.500 distinguished name (X.500dn). IKE can use the X.500dn as an identifier for the remote host, or use one of the certificate's Subject Alternative Names.

Subject Alternative Name

An optional field, X.509 extensions, can contain a Subject Alternative Name field. Although the X.500dn is the most specific way to identify a certificate, the Subject Alternative Name can be used as well, often acting as a simple alias to identify the certificate. If the certificate includes optional X.509v3 extensions, the certificate can contain any or all of the following information:

- IpAdrr - an IP address
- Fqdn - a fully qualified domain name
- UserAtFqdn - an email address

IP security 901
Subject Public Key Info
The public key is used for encrypting information that can be decrypted only with the certificate's private key. Likewise, information that is encrypted using the certificate's private key can be decrypted only with the public key. Using this scheme, information from the owner can be encrypted, digitally signed, and authenticated. IKE uses the public key to assist in verifying a host's identity.

Issuer Name
Certificate signing is a method by which a certificate is verified by a trusted third party. A signed certificate contains the subject name and key identifier of the certificate authority that signed it, known as the issuer.

Because there are many commercial and private certificate authorities, it is possible for a host to own multiple certificates that are signed by different certificate authorities. Depending on a site's policy, only certain certificate authorities might be trusted. Therefore, a z/OS IP security host might request that a peer use only certificates that are signed by a specific trusted certificate authority. Two configuration parameters refer to certificate authorities, the SupportedCertAuth parameter of the IKeConfig statement in the iked.conf file, and the CaLabel parameter of the RemoteSecurityEndpoint statement. The SupportedCertAuth parameter names a specific certificate authority that is recognized by the IKE daemon. The CaLabel parameter identifies a portion of a certificate authority hierarchy that is preferred by the local security endpoint.

For more information about the IkeConfig and RemoteSecurityEndpoint statements, see z/OS Communications Server: IP Configuration Reference.

Pre-shared key
The pre-shared key method of authentication enables a remote host to authenticate itself by providing a secret key, which is known to both hosts. This key is pre-configured by the administrator, and is used along with the Diffie-Hellman shared secret to derive cryptographic keys used to protect and authenticate data that flows during the phase 1 negotiation. The pre-shared key is a shared secret between the two IKE peers, and any host that does not know the shared key cannot enter into negotiation. IKE maintains a list of all the remote hosts that are authorized to negotiate. This list contains the identity of the remote host and the pre-shared key known to that host.

Negotiation modes for phase 1
For IKEv1, the phase 1 negotiation that takes place between two IKE peers happens in one of two modes, Main mode or Aggressive mode.

Main mode is more secure because it encrypts the identities of the two hosts that are contained in the IKE messages, but somewhat slower because more message exchanges are required. Main mode requires a total of six messages, three from the initiator and three from the responder.

Aggressive mode is faster, in that fewer messages are exchanged. Aggressive mode requires only three messages, two from the initiator and one from the responder. However, the identity of the two hosts is not protected in Aggressive mode. An IKE implementation is not required to support Aggressive mode.

The choice of mode depends in part on the security needs of the installation. If it is important that the identities of either host are not to be in clear text on the network, use Main mode. Otherwise, if both hosts support it, you can use Aggressive mode for faster, more efficient key exchange. One limitation of Aggressive mode is that the initiator can specify only a single Diffie-Hellman group because the key exchange data is sent in the first message. If you need to allow the initiator to send multiple offers with different Diffie-Hellman groups, use Main mode.

For IKEv2, there is only one set of network flows defined for phase 1 negotiation. The set requires four messages, two from the initiator and two from the responder. The first two of these four messages flow in the clear on the network; the other two messages are encrypted. The negotiation of the first phase 2 Security Association is accomplished within these four flows; when the fourth message flows, both phase 1 and phase 2 Security Associations are activated. Either the initiator or the responder can subsequently activate additional phase 2 Security Associations using this phase 1 Security Association.

You configure the choice of negotiation mode using the KeyExchangeAction statement and the Diffie-Hellman group using the KeyExchangeOffer statement in an IP security policy configuration file. For more
Phase 2
The purpose of phase 2 negotiation is to establish a set of parameters that are known as a Security Association, which is used to protect specific types of IP traffic. The phase 2 Security Association contains the keys that are used to encrypt and decrypt IPSec packets on the host, authenticate IPSec packets on the host, or both. The phase 2 Security Association is negotiated for a specific set of data endpoints for a specific type of traffic, and contains the following information:

- The keys that are used to encrypt, if encryption is being used
- The keys that are used to authenticate
- The data endpoints, either a single IP address or range of IP addresses
- The protocol of the traffic to be protected, either a single protocol or all protocols
- The ports of the traffic to be protected, either a single port, a range of ports if the IKEv2 protocol is used to negotiate the phase 2 Security Association, or all ports
- The IPSec protocol that is used to protect the data: AH or ESP, or both if the IKEv1 protocol is used for the negotiation
- The type of authentication algorithm to be used
- The type of encryption algorithm to be used, if encryption is being used
- How to build the IPSec packets (tunnel, transport, UDP-encapsulated tunnel, or UDP-encapsulated transport)
- How often the keys should be refreshed, if the IKEv1 protocol is used for the negotiation
- A security parameter index (SPI) value, used together with the remote security endpoint IP address to uniquely identify the Security Association
- The Diffie-Hellman group for perfect forward secrecy (PFS)

A phase 2 negotiation can begin only after the completion of a corresponding phase 1 Security Association. The encryption methods that are agreed upon during the phase 1 negotiation are used to protect the data that is exchanged during the phase 2 negotiation. For instance, if the KeyExchangeRule between two security endpoints specified SHA1 and 3DES, the IKE data that is exchanged during the phase 2 negotiation is authenticated using HMAC-SHA and encrypted using 3DES encryption. Although both phase 1 and phase 2 Security Associations might use the same authentication and encryption methods, this is not required. For instance, a phase 1 Security Association can specify SHA1 authentication and 3DES encryption, while a phase 2 Security Association might use ESP with HMAC-MD5 authentication and DES encryption.

The keys that are generated during the phase 2 negotiation can be derived from the phase 1 master key to amortize the cost of the phase 1 key generation. As an alternative, you can configure the phase 2 negotiation to use perfect forward secrecy (PFS) for stronger security. Each has its advantage as follows:

- If PFS is used, phase 2 negotiation does not derive its keys from the master key, but instead generates new keying material using the Diffie-Hellman algorithm. Because it is independently derived, the resultant phase 2 key is more secure.
- If PFS is not used, phase 2 negotiation is completed much more quickly, but the resultant phase 2 key is less secure.

In either case, phase 2 does not incur the same degree of processing overhead that is involved in phase 1 negotiation with the remote IKE peer.

For IKEv2, the negotiation of the first phase 2 Security Association on a given phase 1 is a special case because it is performed during activation of the phase 1. In this case, the phase 1 Diffie-Hellman group is used for the phase 2 negotiation, regardless of what was defined on the IpDataOffer statement that corresponds to the phase 2.

When phase 2 negotiation has completed, the Security Association is available for use by the stack. Now, any traffic that is mapped to this Security Association by an IP filter rule is IPSec-protected. Because each
phase 2 Security Association corresponds to a single unique phase 1 Security Association, the identity of the remote peer is implicitly authenticated when the phase 2 Security Association is used.

Policy for phase 2 Security Associations is defined by referencing an IpDynVpnAction statement on an IpFilterRule statement. For more details on referencing an IpDynVpnAction statement on an IpFilterRule statement, see z/OS Communications Server: IP Configuration Reference.

You can specify only tunnel or transport mode encapsulation on the IpDataOffer statement. The decision to use UDP-encapsulated transport or tunnel mode is made heuristically by the z/OS IKE daemon. If a NAT device is detected in the process of creating a phase 1 Security Association, all phase 2 Security Associations negotiated under the protection of that phase 1 Security Association are negotiated using UDP encapsulation. In this case, all IpDataOffer statements that contain ESP refer to UDP-encapsulated tunnel or transport mode, as applicable. Any IpDataOffer statements that are configured to use AH authentication are ignored, because the IPSec protocols do not allow for AH authentication when UDP encapsulation is used.

The phase 2 parameter values supported can differ between IPSec implementations. For example, z/OS provides configuration to negotiate a phase 2 Security Association for specific port and specific protocol values. Many implementations of IPSec support negotiating only a wide Security Association, covering all ports and protocols.

**Refreshing phase 1 Security Associations**

Refreshing a Security Association is the process of creating a new Security Association to replace an existing Security Association. The IKED automatically refreshes Security Associations when they are about to expire.

When an IKEv1 phase 1 Security Association is refreshed, the IKED performs the following actions:

- It creates a new Security Association using a main mode or aggressive mode exchange.
- It negotiates new keys and it reauthenticate the identity of the IKE peer.

When an IKEv2 phase 1 Security Association is refreshed, the IKED performs the following actions:

- It creates a new Security Association by using a create child exchange process.
- It negotiates new keys but does not reauthenticate the identity of the IKE peer.

You can use the ReauthInterval parameter on the KeyExchangeAction statement to cause the IKED to periodically reauthenticate an existing IKEv2 phase 1 Security Association. For more information about the KeyExchangeAction statement, see the KeyExchangeAction statement in z/OS Communications Server: IP Configuration Reference.

You can use the refresh option on the `ipsec` command to refresh an existing phase 1 Security Association. When you use the `ipsec` command to refresh an existing IKEv1 or IKEv2 phase 1 Security Association, new keys are negotiated and the identity of the IKE peer is reauthenticated. For more information about the `ipsec` command, see z/OS Communications Server: IP System Administrator's Commands.

**IPSec and network address translation devices**

There are inherent incompatibilities between IPSec and network address translation (NAT) functions. RFC 3715, *IPsec-Network Address Translation (NAT) Compatibility Requirements*, describes the problems that arise when IPSec is used to protect traffic that traverses a NAT. One basic problem is that when IPSec Security Associations traverse a NAT, the NAT is unable to update IP addresses and checksums that are part of the encapsulated data (encrypted, authenticated, or both). See “NATT support level” on page 905 for descriptions of the RFCs that define mechanisms to enable specific uses of IPSec to traverse one or more NAT devices.

When IPSec traverses one or more NAT devices, it is known as NAT traversal (NATT). z/OS Communications Server supports NAT traversal for IPv4 traffic only. NAT traversal is supported for IKEv1 and IKEv2 dynamic tunnels; it is not supported for manual tunnels.
There are several reasons why network address translation might be used. One reason is to economize on the use of public addresses within the internal network, using a public address only when data must be globally routed. A second reason is to hide internal IP addresses from network segments outside the internal IP address domain.

It should be noted that the NAT traversal support, as defined by the IETF, transmits internal IP addresses to its IPSec peer. These internal addresses are not exposed on the external network. However, the internal addresses are available for display at the remote security endpoint. If you are considering using this support, evaluate whether transmitting internal IP addresses to an IPSec peer is acceptable from a security policy perspective.

NAT encompasses the following IP address mapping techniques:

- One technique performs a one-to-one address translation. An internal-external IP address mapping is maintained by the NAT device. IP addresses are translated, but ports are unchanged. The mapping can be static or dynamic. For a static mapping, there is a definition in the NAT that always translates IP address x.x.x.x to IP address y.y.y.y. An outbound packet is not needed to establish the mapping. For a dynamic mapping, the NAT has a pool of IP addresses that are assigned as needed, so IP address x.x.x.x might be mapped to IP address y.y.y.y one time, and to IP address z.z.z.z at another time. The mapping is established when an outbound packet is processed.

- The network address port translation (NAPT) technique uses multiple internal IP addresses that are translated into a single public IP address. As part of this translation process, the TCP and UDP ports in the packets are translated. NAPT is sometimes referred to as port address translation (PAT) or IP masquerade. The mapping is typically dynamic and established in the NAPT when an outbound packet is processed. For example, the NAPT might create a mapping for internal address x.x.x.x port y to external address a.a.a.a port b and a mapping for internal address z.z.z.z port v to external address a.a.a.a port c.

When only one client behind a NAPT has negotiated a Security Association, it is not always possible for the remote peer to detect whether the public address is being used for one-to-one address translation or for NAPT. When multiple clients have active Security Associations, the remote peer can detect when port translation is being performed.

The terms in front of and behind are used to convey which IP address a NAT is translating. When a NAT is said to be in front of a client, it means the client’s address will be translated by the NAT. When a server is said to be behind a NAT, it means that server’s address will be translated by the NAT.

**NATT support level**

z/OS Communications Server supports NAT traversal as defined in RFCs 3947, 3948, and 5996; they define mechanisms that enable IPsec to traverse one or more NAT devices. Platforms that have implemented their NAT traversal support using pre-RFC drafts might not interoperate with implementations that are compliant with RFCs 3947, 3948, and 5996.

- RFC 3947, *Negotiation of NAT-Traversal in the IKE*, allows an IKEv1 daemon to detect when one or more NATs are being traversed.

- RFC 3948, *UDP Encapsulation of IPsec ESP Packets*, defines two IPsec encapsulation modes, UDP-encapsulated tunnel mode and UDP-encapsulated transport mode. These modes facilitate the traversal of IPsec traffic through a NAT by encapsulating ESP packets within a UDP packet.

- RFC 5996, *Internet Key Exchange (IKEv2) Protocol*, specifies how to detect when IKEv2 peers are traversing one or more NATs.

z/OS Communications Server does provide limited support for the following pre-RFC implementations:

- draft-ietf-ipsec-nat-t-ike-02 (pre-RFC draft of RFC 3947), and draft-ietf-ipsec-udp-encaps-02 (pre-RFC draft of RFC 3948)

- draft-ietf-ipsec-nat-t-ike-03 (pre-RFC draft of RFC 3947), and draft-ietf-ipsec-udp-encaps-03 (pre-RFC draft of RFC 3948)
Dynamic structures used to map Security Associations

The negotiation of a phase 2 Security Association results in the dynamic creation of new filters used to map the Security Association to a specific type of traffic. These dynamic filters are then added to the filter table and remain as long as the Security Association is available for use. Additional structures are added to the filter table when the remote security endpoint is behind a NAT.

Anchor filters and dynamic filters

Filters with ipsec actions are flagged as anchor filters. Anchor filters are neither permit or deny rules, but rather serve as place holders for dynamic filters in the ordered list of filter rules. A dynamic filter is an extension of an anchor filter and is created when a phase 2 Security Association is created. Each phase 2 Security Association that is negotiated is associated with two dynamic filters, an inbound filter and an outbound filter. When an IP packet matches an anchor filter rule, there is a secondary search for a matching dynamic filter rule. If one is not found, the packet is denied, unless the packet is an outbound packet and on-demand negotiations are allowed. In that case, an IKE negotiation ensues to create a Security Association and the matching dynamic filter. If a dynamic filter already exists, the action taken is to permit with IPSec processing applied. The dynamic filter rule indicates which Security Association should be used when applying IPSec processing, because there is a one-to-one correspondence between dynamic filter pairs (inbound and outbound) and phase 2 Security Associations. For a sample display of anchor and dynamic filters, see “Displaying active filters with the ipsec command” on page 1020.

NATT anchor and NATT dynamic filters

When the remote peer is behind a NAT, the dynamic anchor still serves as a place holder in the ordered list of filter rules. However, the dynamic filters that are created when a phase 2 Security Association is created are handled differently. When the phase 2 negotiation is successful, the dynamic filter pair that is created contains the 5-tuple information for which the Security Association was negotiated:

• The data endpoints, either a single IP address or range of IP addresses
• The protocol of the traffic to be protected, either a single protocol or all protocols
• The ports of the traffic to be protected, either a single port or all ports

In cases when the remote peer is behind a NAT, this 5-tuple might not be unique for a Security Association. An additional structure, a NATT anchor, is generated to anchor dynamic filters that share the same 5-tuple information. The dynamic filter is then an extension to the NATT anchor and is flagged as a NATT dynamic. For a sample display of NATT anchor and NATT dynamic filters, see “Displaying active filters with the ipsec command” on page 1020.

NAT resolution filters

When the remote peer is behind a NAT, a connection level filter structure is also created for TCP and UDP connections, the NAT resolution filter (NRF). Unlike the NATT anchor and NATT dynamic filters, which are created when the phase 2 Security Association is created, the NRF is created when the first inbound packet is received for the connection over the phase 2 Security Association. The NRF contains a single source and destination IP address, a single source and destination port value, and a single protocol. This connection-level filter is needed to determine the phase 2 Security Association that will be used for outbound data. For a sample display of NAT resolution filters, see “Displaying active filters with the ipsec command” on page 1020.

Remote port translation

When the remote peer is a security gateway behind a NAT, the remote data endpoint of the client is represented by the security gateway's public IP address. From the z/OS server's perspective, multiple clients that are behind the security gateway are all identified by the IP address of their corresponding security gateway, not the client's private IP address. Consequently, if two clients behind the security gateway were to open a connection to the same service (FTP, for example) from the same ephemeral port (1024, for example), the two connections could not be uniquely identified.

Similarly, when the remote peer is a host behind a NAPT, the remote data endpoint of the host is represented by the public address assigned by the NAPT. Typically, multiple hosts that are behind the
NAPT are all assigned the same public IP address, with port translation distinguishing the hosts. The port that is being translated by the NAPT is the port found in the UDP header of the IKE packet and the UDP-encapsulated ESP packet, not the connection port. Consequently, if two hosts behind the NAPT open a connection to the same service (FTP, for example) from the same ephemeral connection port (1024, for example), the two connections cannot be uniquely identified.

Traditionally, the combination of local and remote IP addresses and ports is enough to distinguish the connections; in these instances, because the connection requests appear to be coming from the same IP address, they look identical. To avoid such conflicts, Communications Server provides remote port translation for TCP and UDP connections when needed. Without remote port translation, the first inbound TCP connection request for a unique 5-tuple would succeed. However, a subsequent inbound connection request using the same 5-tuple would fail. Communications Server's remote port translation allows subsequent inbound connections using the same 5-tuple to succeed by translating the remote port value to a different ephemeral port.

Remote port translation does not need to be configured or enabled. It is built into Communications Server's NAT traversal support and is always in effect when the remote peer is behind a NAT. When a remote port is translated, message EZD0827I, remote port translated, is logged. Remote port translation determines whether the source port in an inbound packet represents a duplicate port. If it does, an attempt is made to assign an unused ephemeral port value. If the inbound packet matches a configured filter rule that covers all ports, any unused ephemeral port value can be assigned. If the configured filter rule applies only to a range of ports, the remote port is translated only to an unused ephemeral port in that range. If an unused port cannot be found, the connection request fails. When a remote port value is translated, there is both an original remote port and translated remote port for a connection. Various commands, such as Netstat, enable you to view connection information including the port, or even to select display data based on port. For connection data, if only one remote port is being provided, the translated port is displayed or used for a selection, if remote port translation has been done.

The `ipsec -o display` command provides a display of port mappings in effect. For a sample display of remote port translation, see “Displaying remote port translation with the ipsec command” on page 1035.

### Steps for preparing the z/OS system for IP security

Establish the security needs for your installation. Set up key required applications, modify default IP filter policy if necessary, configure the IKE daemon, configure the NSS daemon and additional encryption products as needed, and create IP security policy configuration files.

**Before you begin**

You need to be familiar with the concepts of IP filter logging and IPSec protection. See “Overview of using IP security” on page 860. You also need to be familiar with the commands used to administer IP security. See “Commands used to administer IP security” on page 859.

**Procedure**

Perform the following steps to prepare the z/OS system for IP security.

1. Develop a site policy to address the security needs of your installation.
   
   Consider the following questions before beginning to build a robust IP security policy:
   
   - Do you want a default-allow or default-deny policy?
   - If you want a default-deny policy, what traffic is allowable as critical to the correct functioning of the system?
   - What hosts are allowed to send data to the secure host?
   - Do you understand the network topology, and where the communicating hosts are located within the network?
   - Are there network address translation (NAT) devices in the network topology?
   - What type of traffic is allowable from those hosts?
• What general network services that rely on well-known ports do you want to allow?
• Will you forward any packets you receive that are not destined for you?
• Who is allowed to configure the IP security policy?
• Are you running with one TCP/IP stack, or more than one TCP/IP stack?
• Are you running IPv6 traffic?
• Will all TCP/IP stacks share the same policy definitions, or will they have unique differences?
• Will traffic that is sent or received by the secure host traverse the Internet?
• Do you want to participate in a VPN? (If so, IPSec is required.)

If IPSec is required:
– What are the IPSec capabilities of the remote endpoints?
– How do you want to authenticate participating hosts:
  - Pre-shared key?
  - Digital signature? (requires digital certificates)
– What type of authentication is needed for the data that is involved?
– Is encryption needed for the data that is involved, and how strong should the encryption algorithms be?
– Will all participating hosts use the same level of data encryption and authentication, or do you need to define unique policies for individual hosts?

2. Identify the resources to be secured.

Create a worksheet for each TCP/IP stack you will enable for IP security. This information aids in determining which interfaces and connected networks are secured. You can later use the information from the worksheets to provide values for IP security policy configuration statements. Figure 116 on page 908 includes a sample worksheet:

<table>
<thead>
<tr>
<th>Host name of z/OS system</th>
<th>________________________________</th>
</tr>
</thead>
<tbody>
<tr>
<td>TCP/IP stack name</td>
<td>_____<strong><strong><strong>IPSECURITY-enabled (Y/N)</strong></strong></strong></td>
</tr>
<tr>
<td>Network interface(s)</td>
<td></td>
</tr>
<tr>
<td>IPv4 address/Mask</td>
<td>Security Class_______</td>
</tr>
<tr>
<td>IPv4 address/Mask</td>
<td>Security Class_______</td>
</tr>
<tr>
<td>IPv4 address/Mask</td>
<td>Security Class_______</td>
</tr>
<tr>
<td>IPv6 address/Prefix</td>
<td>Security Class_______</td>
</tr>
<tr>
<td>Virtual IPv4 address/Mask</td>
<td>Security Class_______</td>
</tr>
<tr>
<td>Virtual IPv4 address/Mask</td>
<td>Security Class_______</td>
</tr>
<tr>
<td>Virtual IPv6 address/Pref</td>
<td>Security Class_______</td>
</tr>
<tr>
<td>Virtual IPv6 address/Pref</td>
<td>Security Class_______</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Identities, other than IP address, by which the IKE daemon will be known (e.g., X500dn, Fqdn, UserAtFqdn, KeyID)</th>
<th>______________</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>--------------</td>
</tr>
<tr>
<td></td>
<td>--------------</td>
</tr>
<tr>
<td></td>
<td>--------------</td>
</tr>
</tbody>
</table>

Figure 116. Sample worksheet for stack security

Security class is an optional designation for a network interface. You can assign network interfaces a security class (1-255) that is used to group interfaces with similar security requirements. This concept is an extension of the traditional notion of secure and nonsecure interfaces, to allow for more than two classes. The secure and nonsecure model can still apply if only two security classes are defined.

Complete a table of remote hosts and subnetworks with which this host needs to transfer data, as shown in Table 50 on page 909. The remote hosts can optionally be grouped in a user-defined zone.
to simplify the number of IP filter rules that are required. For instance, you might want to define an
internal, external, trusted, Internet, partner company, or other zone that has meaning to your site.

**Rule:** If the remote IKE peer is on a security gateway to the remote host, the IP address of the remote
host might not match the IP address of the remote IKE peer. If this is the case, tunnel-mode
encapsulation of IPSec traffic is required.

### Table 50. Table of remote hosts and subnetworks

<table>
<thead>
<tr>
<th>Remote IP address or subnet</th>
<th>User-defined zone of remote hosts</th>
<th>Identity of remote IKE peer (IpAddr, X500dn, KeyID, Fqdn, or UserAtFqdn)</th>
<th>IP address of remote IKE peer</th>
<th>Allowed list of services (Telnet, FTP, web, EE, ALL, or other)</th>
<th>Security action (permit, deny, ipsec)</th>
<th>IPSec security level, if applicable</th>
</tr>
</thead>
</table>

3. Modify the default IP filter policy (optional).

After the site policy is established, you can modify the default IP filter policy if necessary. For a
description and examples of how to modify the default IP filter policy, see “Default IP filter policy and
IP security policy” on page 873.

**Guideline:** You should define IPSECRULE and IPSEC6RULE statements that permit access from at
least one administrative machine. In the event that Policy Agent is unavailable, or the IP security
configuration files contain errors, the active default policy would deny access to the IP security-enabled stack. Should this situation occur, if you have added the appropriate IPSECRULE and
IPSEC6RULE statements to the default policy, you can still access the secure z/OS host and make the
necessary administrative changes to correct the problem.

4. Set up the key required applications:

- **TCP/IP**
  
  To enable IP security on a z/OS stack, make the following changes in the TCP/IP profile:
  
  – Add IPCONFIG IPSECURITY.
  – To also enable IP security for IPv6, add IPCONFIG6 IPSECURITY.
  – Reserve ports 500 and 4500 for IP security. If the IKE daemon is running on this system, reserve
    the ports for the user ID under which the IKE daemon is running. In this example, the IKE daemon
    is running under the IKED user ID:

    | Port | Protocol | User ID |
    |------|----------|---------|
    | 500  | UDP      | IKED    |
    | 4500 | UDP      | IKED    |

    If the IKE daemon is not running on this system, reserve the ports by specifying RESERVED:

    | Port | Protocol | User ID |
    |------|----------|---------|
    | 500  | UDP      | RESERVED|
    | 4500 | UDP      | RESERVED|

  – To direct IPsec's AH and ESP protocol processing to zIIPs, add GLOBALCONFIG ZIIP IPSECURITY.

  For information on the IPCONFIG, IPCONFIG6, GLOBALCONFIG, and PORT statements, see z/OS
  Communications Server: IP Configuration Reference.

- **Policy Agent**
  
  For information on configuring the Policy Agent, see Chapter 14, “Policy-based networking,” on page
  761.

- **TRMD**
For information on configuring TRMD, see “TRMD” on page 851.

• Syslogd

For information on configuring the syslog daemon, see “Configuring the syslog daemon” on page 199.

• IKED

The IKED can be started from a z/OS UNIX command line or as an MVS procedure. The iked.conf file controls the overall function of the IKE daemon, such as the following settings:

– The logging level of the IKE daemon
– The logging level of the Policy Agent when performing IP security-related tasks on behalf of the IKE daemon
– The name of the RACF key ring that is owned by the IKE daemon
– Whether IKE messages are echoed to STDOUT when the daemon is started for the UNIX System services shell
– How long to wait when attempting to connect to the Policy Agent
– The list of certificate authorities that are acceptable for RSA signature negotiation when the IKED is using the native certificate service (when the Network Security Services (NSS) server is providing the certificate service, this list is not used)

Most of the configuration parameters have a default value and do not require modification.

**Rule:** If the RSA signature method is to be used in any IKE phase 1 negotiation and the IKED is using the native certificate service, the name of the IKE key ring must be included in the iked.conf file. If the NSS server is providing the certificate service, the IKE key ring name is not needed.

**Tip:** If the RSA signature method is used and the IKED is using the native certificate service, including a list of supported certificate authorities enhances the performance of certificate searches.

**Guideline:** You should not change the logging levels of the IKE daemon (IkeSyslogLevel) and Policy Agent (PagentSyslogLevel) from their default values for normal day-to-day operation. Higher logging levels can affect performance and should be used for temporary diagnostic purposes only. The default PagentSyslogLevel value 0 prevents the IKE daemon from logging diagnostic information about its interactions with Policy Agent. The default IkeSyslogLevel value 1 provides basic informational and error messages. You can set the IkeSyslogLevel value to 0 to disable IKE syslog messages entirely (for both the IKE daemon and Policy Agent; to collect PagentSyslogLevel tracing, the IkeSyslogLevel value must also be a nonzero value). You can set the IkeSyslogLevel value to a higher value to identify the source of an error; for example, if you experience problems with Security Association negotiations that are caused by a configuration error, you might enable IkeSyslogLevel 4 (debugging information for Security Association negotiations).

For detailed syntax and a description of the iked.conf file, and details on starting the IKE daemon as an MVS procedure, see z/OS Communications Server: IP Configuration Reference.

5. Define access controls for key required applications:

• TRMD

TRMD runs as an authorized program and requires RACF setup. TRMD must be able to run as a started task and have superuser authority. For sample RACF commands, see the EZARACF member of SEZAINST.

• Policy Agent

Policy Agent runs as an authorized program and requires RACF setup. Policy Agent must be able to run as a started task and have superuser authority. For sample RACF commands, see the EZARACF member of SEZAINST and “Step 1: Configure general information” on page 780.

• IKED

For the steps to prepare for running the IKE daemon, see Appendix E, “Steps for preparing to run IP security,” on page 1331.
6. Configure the IKE daemon.
   See Appendix E, “Steps for preparing to run IP security,” on page 1331.

7. (Optional) Configure the NSS daemon.
   If the IKED is using the NSS certificate service for any IKEv1 or IKEv2 Security Association negotiation, then configure the NSS daemon. The IKED must use the NSS certificate service for any IKEv2 negotiation that uses certificates for authentication. The IKED can use either the native certificate service or the NSS certificate service for an IKEv1 negotiation that uses certificates for authentication.

   For more information about the NSS daemon, see Chapter 18, “Network security services,” on page 1055.

8. (Optional) Configure additional encryption products.
   • 3DES support
     For 3DES (triple DES), the Communications Server Security Level 3 feature, is required.
   • AES support (including AES-CBC, AES-GCM and AES-GMAC)
     For AES, the Communications Server Security Level 3 feature and the z/OS Security Level 3 feature are required and ICSF must be started.
   • FIPS 140
     For IKED, NSSD, and TCP/IP to run in FIPS 140 mode, you must first choose one of several modes of FIPS operation for ICSF and start ICSF.

     **Requirement:** ICSF must be active before starting the IKE daemon or NSS server configured in FIPS 140 mode. For information about enabling ICSF to support FIPS 140-2, see the topic about operating in compliance with FIPS 140-2 in z/OS Cryptographic Services ICSF Writing PKCS #11 Applications.
   • ICSF
     There are several options available on z/OS to perform encryption in hardware. The ICSF product is required to support these various options. For a description and information about how to configure these options, see z/OS Cryptographic Services ICSF Administrator's Guide.

     For the RACF commands that authorize ICSF, see Appendix E, “Steps for preparing to run IP security,” on page 1331.
   • SHA2 support (including SHA2-256, SHA2-384, and SHA2-512, as well as all corresponding HMAC-SHA2 algorithms) and AES authentication (AES-XCBC)

     For SHA2 and AES-XCBC authentication, ICSF must be started.

9. Create IP security policy configuration files.
   After the security needs of your installation are established, the next step is to create one or more IP security policy configuration files. There are two main configuration files in which IP security policy configuration is stored:

   **Stack-specific IP security configuration file**
   Configured on a per-stack basis and contains only IP security policy configuration that applies to the stacks for which it is configured.

   **Common IP security configuration file**
   Contains IP security policy configuration that applies to every stack on the system and can be used to hold shared definitions.

   The stack-specific file can refer to various definitions in the common file, and can override policy definitions in the common file.

   Although Policy Agent uses LDAP to store policy for some other policy types, IP security policy configuration is stored exclusively in human-readable text files, either in the z/OS UNIX file system or in an MVS data set. These configuration files are then read by Policy Agent when it initializes and before being installed into the stack.
IP security policy configuration

This topic describes the general steps for creating IP security policy configuration files for the most common configurations. Configuring a complete and specific IP security policy that meets the needs of any installation is beyond the scope of this text, but guidance for more advanced configurations is provided.

“Overview of configuring IP security policy” on page 912 describes the common IP security configuration file, the stack-specific IP security configuration file, and the general content, structure, and use of these files.

“Component policies of IP security policy configuration files” on page 919 describes the types of policies contained in IP security policy configuration files.

“Steps for configuring IP security policy” on page 944 describes the steps for manually creating IP security policy configuration files.

“Quick start using IP filtering and IPSec host-to-host” on page 930 describes a complete IP security policy allowing connections from a secure server to an administrative machine on an internal network, and represents the minimum configuration needed to provide IPSec protection with dynamic key management between two hosts. This topic also describes the use of the `ipsec` command to display filters and Security Associations.

“Configuring specific security models” on page 946 provides more examples and describes the configuration needed for common security models.

Overview of configuring IP security policy

There are three options for IP security policy configuration for a system:

• Use a common IP security configuration file that applies to all stacks on the system, enforcing a consistent policy. In this instance, a stack-specific IP security configuration file is not necessary.

• Use a unique and separate stack-specific IP security configuration file for each stack on the system. In this instance, a common IP security configuration file is not necessary.

• Use both a common and a stack-specific IP security configuration file.
  – The common IP security configuration file can be used as a common repository for frequently used definitions, which can be referenced by any stack-specific IP security configuration file.
  – The stack-specific IP security configuration file can contain unique statements that apply only to the stack for which it is configured, and can reference statements that are defined in the common IP security configuration file.

Although not an error, note that when using the last approach, it is possible for duplicate statements to exist in the common and the stack-specific IP security configuration files (for example, two IpFilterRule statements with the same name). In this case, the statement in the stack-specific IP security configuration file is honored. Statements in the stack-specific IP security configuration file always take precedence over the common IP security configuration file.

Structure of an IP security configuration file

The common IP security configuration file and the stack-specific IP security configuration file have exactly the same structure. They are comprised of a number of statements that define items that are used to define policy, such as policies, rules, actions, groups, and objects. Statement names and attribute names are not case sensitive, though they appear in mixed case in this information for readability. Only user-defined names are case sensitive. For the complete syntax of all IP security policy statements, see z/OS Communications Server: IP Configuration Reference.

An IP security policy configuration statement has the following generic form:

```
StatementType     user-defined name
{                      
  Attribute1     value1

```
Statements often contain other inline statements in a recursive form:

```
StatementType1  user-defined name
{
  Attribute1  value1
  StatementType2  optional user-defined name
  {
    Attribute1  value1
    Attribute2  value2
  }
  Attribute2  value2
}
```

There are three main sections in an IP security configuration file, identified by the following three statements:

- IpFilterPolicy
- KeyExchangePolicy
- LocalDynVpnPolicy

Additional statements that define rules, actions, groups, and objects are found both in the main body of the configuration file and within any of these other three policy blocks. A high-level view of an IP security configuration file follows. Although the statement blocks are shown in a specific order, the ordering is arbitrary.

```
IpFilterPolicy #(required)
{
  <local statements>
}
KeyExchangePolicy #(optional)
{
  <local statements>
}
LocalDynVpnPolicy #(optional)
{
  <local statements>
}
<global statements>
```

**Groups**

Groups provide a method to combine related objects in a meaningful way into sets. The following IP security policy configuration statements can be used as groups:

- IpAddrGroup
- IpFilterGroup
- IpServiceGroup
- KeyExchangeGroup
- LocalDynVpnGroup

**Reference statements**

A reference statement can be recognized by the suffix Ref. References provide a convenient way to reuse definitions, eliminating the need to repeatedly specify things such as host addresses and common services. Nearly all statements in the IP security configuration file can be referenced, and all action statements must be referenced. To be referenced, an IP security policy configuration statement must be given a user-defined name. Names of statements can be up to 32 characters. The following IP security policy configuration statements can be referenced, and therefore reused:
Steps for configuring local IP security policy using only a common IP security configuration file

You can configure local IP security policy for all stacks on the system using only a common IP security configuration file. In this instance, a stack-specific IP security configuration file is not necessary.

**Procedure**

Perform the following steps to configure local IP security policy using only a common IP security configuration file.

1. In the main Policy Agent configuration file, include a CommonIpSecConfig line that identifies the common IP security configuration file, as follows:

   ```
   CommonIpSecConfig /etc/common.ipsecpol
   ```

2. In the main Policy Agent configuration file, include a line with the TcpImage statement for each IP security stack to be configured:

   ```
   TcpImage TCPCS /etc/TCPCS.image
   TcpImage TCPCS2 /etc/TCPCS2.image
   ```

3. In each configuration file that was identified on the TcpImage statement shown in step “2” on page 914, include a line that contains IpSecConfig with no file name, as follows:

   ```
   In /etc/TCPCS.image:
   IpSecConfig
   ```
   ```
   In /etc/TCPCS2.image:
   IpSecConfig
   ```
Results
All stacks on the z/OS system will adhere to the policy that is specified in the /etc/common.ipsecpol file.

Steps for configuring remote IP security policy using only a common IP security configuration file
You can configure remote IP security policy for all stacks on the z/OS policy client system using only a common IP security configuration file. In this instance, a stack-specific IP security configuration file is not necessary.

Procedure
Perform the following steps to configure remote IP security policy using only a common IP security configuration file.
1. In the main Policy Agent configuration file on the policy client, include the ServerConnection statement, and a line with the TcpImage statement for each IP security stack to be configured:

   ```
   ServerConnection
   { ...
   } TcpImage TCPCS /etc/TCPCS.image
   TcpImage TCPCS2 /etc/TCPCS2.image
   ...
   ```

2. In each configuration file that was identified on the TcpImage statement shown in step 1, include a PolicyServer statement.
   For example, in /etc/TCPCS.image:

   ```
   PolicyServer
   { 
   ClientName IPSecClientTCPCS
   PolicyType IPSec 
   { 
   -- ...
   } 
   }
   ```

   In /etc/TCPCS2.image:

   ```
   PolicyServer
   { 
   ClientName IPSecClientTCPCS2
   PolicyType IPSec 
   { 
   -- ...
   } 
   }
   ```

3. In the main configuration file on the policy server, include a DynamicConfigPolicyLoad statement, as follows:

   ```
   DynamicConfigPolicyLoad IPSecClient.*
   { 
   PolicyType IPSec 
   { 
   CommonPolicyLoad /etc/common.ipsecpol
   } 
   } 
   ```

Results
All stacks on the z/OS policy client system will adhere to the policy that is specified in the /etc/common.ipsecpol file on the policy server.
Steps for configuring local IP security policy using only a stack-specific IP security configuration file

You can configure local IP security policy using only a unique and separate stack-specific IP security configuration file for each stack on the system. In this instance, a common IP security configuration file is not necessary.

Procedure

Perform the following steps to configure local IP security policy using only a stack-specific IP security configuration file.

1. In the main Policy Agent configuration file, include a line with the TcpImage statement for each stack to be configured, as follows:

   ```
   TcpImage TCPCS /etc/TCPCS.image
   TcpImage TCPCS2 /etc/TCPCS2.image
   ...
   ```

2. In each configuration file that was identified on the TcpImage statement shown in step “1” on page 916, include an IPSecConfig line that identifies the stack-specific IP security configuration file, as follows:

   ```
   In /etc/TCPCS.image:
   IpSecConfig /etc/TCPCS.ipsecpol
   In /etc/TCPCS2.image:
   IpSecConfig /etc/TCPCS2.ipsecpol
   ```

Results

Each stack on the z/OS system will adhere to the policy that is specified by its unique policy file. Stack TCPCS uses the policy that is configured in /etc/TCPCS.ipsecpol, and stack TCPCS2 uses the policy that is configured in /etc/TCPCS2.ipsecpol.

Steps for configuring remote IP security policy using only a stack-specific IP security configuration file

You can configure remote IP security policy using a unique and separate stack-specific IP security configuration file for each stack on the z/OS policy client system. In this instance, a common IP security configuration file is not necessary.

Procedure

Perform the following steps to configure remote IP security policy using only a stack-specific IP security configuration file.

1. In the main Policy Agent configuration file on the policy client, include the ServerConnection statement, and a line with the TcpImage statement for each IP security stack to be configured:

   ```
   ServerConnection
   {
   
   }
   TcpImage TCPCS /etc/TCPCS.image
   TcpImage TCPCS2 /etc/TCPCS2.image
   ...
   ```

2. In each configuration file that was identified on the TcpImage statement shown in step 1, include a PolicyServer statement.
   For example, in /etc/TCPCS.image:

   ```
   PolicyServer
   {
   
   }
In /etc/TCPCS2.image:

```
PolicyServer
{
    ClientName IPSecClientTCPCS2
    PolicyType IPSec
    {
        
    }
    
}
```

3. In the main configuration file on the policy server, include DynamicConfigPolicyLoad statements, as follows:

```
DynamicConfigPolicyLoad IPSecClientTCPCS
{
    PolicyType IPSec
    {
        PolicyLoad /etc/TCPCS.ipsecpol
    }
    
} DynamicConfigPolicyLoad IPSecClientTCPCS2
{
    PolicyType IPSec
    {
        PolicyLoad /etc/TCPCS2.ipsecpol
    }
    
}
```

**Results**

Each stack on the z/OS policy client system will adhere to the policy that is specified by its unique policy file. Stack TCPCS uses the policy that is configured in /etc/TCPCS.ipsecpol on the policy server, and stack TCPCS2 uses the policy that is configured in /etc/TCPCS2.ipsecpol on the policy server.

**Steps for configuring local IP security policy using both a stack-specific file and a common file**

You can configure local IP security policy using both a stack-specific file and a common file. If there are duplicate statements, the stack-specific file always takes precedence over the common file.

**Procedure**

Perform the following steps to configure local IP security policy using both a stack-specific IP security configuration file and a common IP security configuration file.

1. In the main Policy Agent configuration file, include a CommonIpSecConfig line that identifies the common IP security configuration file, as follows:

```
CommonIpSecConfig /etc/common.ipsecpol
```

2. In the main Policy Agent configuration file, include a line with the TcpImage statement for each stack to be configured, as follows:

```
TcpImage TCPCS /etc/TCPCS.image
TcpImage TCPCS2 /etc/TCPCS2.image
```
3. In each configuration file that was identified on the TcpImage statement in step “2” on page 917, include an IPSecConfig line that identifies the stack-specific IP security configuration file, as follows:

<table>
<thead>
<tr>
<th>Configuration File</th>
<th>IPSecConfig Line</th>
</tr>
</thead>
<tbody>
<tr>
<td>/etc/TCPCS.image</td>
<td>IPSecConfig /etc/TCPCS.ipsecpol</td>
</tr>
<tr>
<td>/etc/TCPCS2.image</td>
<td>IPSecConfig /etc/TCPCS2.ipsecpol</td>
</tr>
</tbody>
</table>

**Results**

Any statements in the common IP security configuration file are added to the policy for each stack when the policy is initialized. Either file, /etc/TCPCS.ipsecpol or /etc/TCPCS2.ipsecpol, can refer to statements in /etc/common.ipsecpol. In the case of duplicate names, any named statement in the stack-specific IP security configuration file overrides a statement with the same name in the common IP security configuration file.

**Steps for configuring remote IP security policy using both a stack-specific file and a common file**

You can configure remote IP security policy using both a stack-specific file and a common file. If there are duplicate statements, the stack-specific file always takes precedence over the common file.

**Procedure**

Perform the following steps to configure remote IP security policy using both a stack-specific IP security configuration file and a common IP security configuration file.

1. In the main Policy Agent configuration file on the policy client, include the ServerConnection statement, and a line with the TcpImage statement for each IP security stack to be configured:

   ```
   ServerConnection
   {
   ...
   }
   TcpImage TCPCS /etc/TCPCS.image
   TcpImage TCPCS2 /etc/TCPCS2.image
   ...
   
   ```

2. In each configuration file that was identified on the TcpImage statement shown in step 1, include a PolicyServer statement.

   For example, in /etc/TCPCS.image:

   ```
   PolicyServer
   {
   ClientName IPSecClientTCPCS
   PolicyType IPSec
   {
   ...
   }
   ...
   }
   
   ```

   In /etc/TCPCS2.image:

   ```
   PolicyServer
   {
   ClientName IPSecClientTCPCS2
   PolicyType IPSec
   {
   ...
   }
   
   ```
3. In the main configuration file on the policy server, include DynamicConfigPolicyLoad statements, as follows:

```plaintext
DynamicConfigPolicyLoad  IPSecClientTCPCS
{
    PolicyType IPSec
    {
        CommonPolicyLoad /etc/common.ipsecpol
        PolicyLoad /etc/TCPCS.ipsecpol
    }
}
DynamicConfigPolicyLoad  IPSecClientTCPCS2
{
    PolicyType IPSec
    {
        CommonPolicyLoad /etc/common.ipsecpol
        PolicyLoad /etc/TCPCS2.ipsecpol
    }
}
```

**Results**

Any statements in the common IP security configuration file are added to the policy for each stack when the policy is initialized. Either file, /etc/TCPCS.ipsecpol or /etc/TCPCS2.ipsecpol, can refer to statements in /etc/common.ipsecpol. In the case of duplicate names, any named statement in the stack-specific IP security configuration file overrides a statement with the same name in the common IP security configuration file.

**Component policies of IP security policy configuration files**

There are three types of policies in IP security policy configuration files:
- IP filter policy (IpFilterPolicy statement)
- Key exchange policy (KeyExchangePolicy statement)
- Local dynamic VPN policy (LocalDynVpnPolicy statement)

**IP filter policy**

An IP filter policy can stand alone to provide IP filtering and IPSec protection with manual key management. Used in conjunction with the two other policies, it is also required to provide IPSec protection with dynamic key management (IKE). Because filtering is crucial to secure traffic on a host, an IP security policy that contains no IpFilterPolicy statement block or an empty IpFilterPolicy statement block is considered an error, leaving the default policy that is provided by the stack in effect.

The IpFilterPolicy statement block consists of:
- A set of global configuration options
- An ordered list of IP filter rules (IpFilterRule statements)

The purpose of the global configuration options is to control global policy items, such as whether logging is active or whether on-demand Security Association negotiations are allowed, and so forth. These global options apply to all of the IP filter rules that are contained in the policy. Each IP filter rule, in turn, contains data endpoints, traffic descriptions, and actions. When a packet entering or leaving the system matches the data endpoints and traffic description in an IP filter rule, the associated action is taken. If the action is an ipsec action, additional action statements are coded that define the parameters of the IPSec Security Association.

The following sample IpFilterRule statement allows web traffic on an internal server, and references a description of each line in the sample:

```plaintext
1  IpFilterRule             InternalNetWeb
2       {
3          IpSourceAddr          9.1.1.1
4          IpDestAddrSet         9.1.1.0/24
5          IpService
919 IP security
```
Line | Description
--- | ---
1 | The IpFilterRule keyword, followed by a required user-defined name for this rule.
2 | An open brace ({) marks the start of an IpFilterRule statement block.
3 | The source address of the rule. Outbound IP packets that match this rule must have 9.1.1.1 as the source address in the IP header.
4 | The destination address of the rule. Outbound IP packets that match this rule must have an address in the range of 9.1.1.0 - 9.1.1.255 as the destination address in the IP header.
5 | The IpService statement block describes the type of traffic that is allowed between the two data endpoints. The IpService block in this rule is inline to the rule, meaning that the entire definition of the IP service is included within the rule. Many policy statements, including the IpService statement, can be referenced rather than included inline.
6 | An open brace ({) marks the start of the IpService statement block.
7 | The range of source ports that is allowed for outbound packets. The value can be a single number, or a range of ports.
8 | The range of destination ports that is allowed for outbound packets. The value can be a single number, or a range of ports.
9 | The specific protocol that is allowed by this rule.
10 | The direction specification for the IP packet.

Bidirectional indicates that this rule allows outbound traffic from local address 9.1.1.1 on local port 80 to any address in subnet 9.1.1.0/24 using any ephemeral port (that is, 1024-65535), and inbound traffic from any address in subnet 9.1.1.0/24 using any ephemeral port to local address 9.1.1.1 on local port 80. Without the use of the bidirectional keyword, it would be necessary to create two filter rules, one for outbound traffic and one for inbound traffic.

InboundConnect indicates that the rule will match inbound TCP connection attempts as well as bidirectional data on an established connection, but it will not match outbound TCP connection attempts.
11 | The routing information for a packet matching this rule. For a packet to match this rule, the traffic must be local. In other words, this rule does not allow any packets that must be forwarded to another network node. Possible values are local, routed, or either.
12 | The security class of the interface on which the packet must arrive or leave. The security class of an interface is defined using the SECCLASS parameter on the statement that is used to define the
interface in the TCP/IP profile (that is, the LINK, INTERFACE, IPCONFIG DYNAMICXCF, or IPCONFIG6 DYNAMICXCF statement). Each interface on the system can be assigned a SECCLASS in the range 1 – 255. If the SECCLASS parameter is not coded in the TCP/IP profile for an interface, by default the interface is SECCLASS 255. In the SecurityClass parameter in this example, the value 0 indicates that a packet that matches this rule is not restricted and can traverse any interface (1 – 255).

13

A close brace (}) marks the end of the IpService block.

14

The action that is taken on a packet that matches this rule. In this case, permit the packet and log all occurrences of a match. All IP filter rules must include an IpGenericFilterActionRef statement. The IpGenericFilterAction statement itself should be defined elsewhere, outside of the IpFilterRule block, either in the common or the stack-specific IP security configuration file:

```
IpGenericFilterAction     permit-nolog
{                        
  IpFilterAction          permit
  IpFilterLogging         no
}
```

15

A close brace (}) marks the end of the IpFilterRule statement block.

**Rule:** Do not include policy action statements inline. They must be referenced.

**Example 1**

Permit rule allowing outbound FTP client connections from the local host (9.1.1.1) to a remote FTP server (9.1.1.2):

```
IpFilterRule              FTP-client
{                        
  IpSourceAddr           9.1.1.1
  IpDestAddr             9.1.1.2
  IpService              
    {                    
      SourcePortRange     1024 65535
      DestinationPortRange 21
      Protocol             tcp
      Direction            bidirectional OutboundConnect
      Routing              local
      SecurityClass        0
    }
  IpService              
    {                    
      SourcePortRange     1024 65535
      DestinationPortRange 20
      Protocol             tcp
      Direction            bidirectional InboundConnect
      Routing              local
      SecurityClass        0
    }
  IpGenericFilterActionRef  permit
}
```

Normal (non-passive mode) FTP requires that the FTP client be allowed to initiate outbound connections to port 21, and be able to receive inbound connections from port 20. The IpGenericFilterAction permit block must be defined elsewhere, in either the common or the stack-specific IP security configuration file:

```
IpGenericFilterAction     permit
{                        
  IpFilterAction          permit
}
```
**Example 2**

Deny rule that blocks all traffic from all private address spaces that is inbound to a public interface:

```plaintext
IpFilterRule deny-private
{
  IpSourceAddrGroupRef PrivateAddrs
  IpDestAddr all
  IpService
    {
      SourcePortRange 0
      DestinationPortRange 0
      Protocol all
      Direction inbound
      Routing either
      SecurityClass 0
    }
  IpGenericFilterActionRef deny-log
}
```

The `IpSourceAddrGroupRef` parameter references an IP address group that is presumed to be defined elsewhere, in either the common or the stack-specific IP security configuration file:

```plaintext
IpAddrGroup PrivateAddrs
{
  IpAddrSet
    {
      Prefix 10.0.0.0/8
    }
  IpAddrSet
    {
      Prefix 172.16.0.0/12
    }
  IpAddrSet
    {
      Range 192.168.0.0-192.168.255.255
    }
}
```

The `IpGenericFilterActionRef` parameter references an `IpGenericFilterAction` statement that is presumed to be defined elsewhere, in either the common or the stack-specific IP security configuration file:

```plaintext
IpGenericFilterAction deny-log
{
  IpFilterAction deny
  IpFilterLogging yes
}
```

**Example 3**

An ipsec rule that requires IPSec protection for all traffic between the secure server and an administrative machine on the internal network:

```plaintext
IpFilterRule Rule2Admin
{
  IpSourceAddrRef InternalServerAddressA1
  IpDestAddrRef AdminClient
  IpServiceRef All-traffic-local
  IpGenericFilterActionRef ipsec
  IpDynVpnActionRef Silver-TransportMode
}
```

The use of multiple references in this example makes the IP filter rule easier to read. For each referenced object or action, there should be a corresponding definition elsewhere, in either the common or the stack-specific IP security configuration file:

```plaintext
IpAddr InternalServerAddressA1
{
  Addr 9.1.1.1
}
IpAddr AdminClient
```
Addr                 9.1.1.2
}                          
IpService              All-traffic-local
{                          
  Protocol             all
  Direction           bidirectional
  Routing            local
  SecurityClass       0
}
IpGenericFilterAction    ipsec
{                          
  IpFilterAction       ipsec
  IpFilterLogging     yes LogDeny
}
IpDynVpnAction          Silver-TransportMode
{                          
  Initiation         either
  InitiateWithPfs    None
  AcceptablePfs      None
  IpDataOfferRef     SHA-DES-Transport
}
IpDataOffer             SHA-DES-Transport
{                          
  HowToEncap          transport
  HowToEncrypt        DES
  HowToAuth           ESP HMAC_SHA1

**IP filter rule order**

“Example 1” on page 921, “Example 2” on page 922, and “Example 3” on page 922 show individual IP filter rules. A complete IP filter policy contains any number of IP filter rules, configured in much the same manner. It is important to remember that IP filter rules in an IP filter policy are searched in the order listed. Because it is possible for a packet to match more than one rule, a search for a matching filter rule stops after the first match is found, even if there are additional matches further down in the list. Use the `ipsec` command traffic test option (`ipsec -t`) as an aid in determining which IP filter rule an IP packet matches.

The command-line arguments to the `ipsec -t` command are a set of characteristics that describe a particular IP packet. The existing set of filter rules are searched for potential matches. Unlike normal filter processing, which stops the search after a match is found, the `ipsec -t` command displays all matching filter rules. Input to the `ipsec -t` command does not have to specify all possible filtering criteria from an IP packet. The output of the `ipsec -t` command must be inspected to determine which of the returned rules match for a given case.

For instance, an IP filter rule for ICMP can be configured for a specific type and code value, while the traffic test does not provide ICMP type and code as inputs. If more than one IP filter rule matches on the ICMP protocol, they are all displayed. You must determine, from among those listed, which rule applies for a specific IP packet.

For a complete description of the `ipsec` command, including the `ipsec -t` option, see z/OS Communications Server: IP System Administrator’s Commands.

**Key exchange policy**

A key exchange policy is required by IKE to provide dynamic key management. The policy contains the definitions about how the negotiation of keys is to be performed (using IKEv1 or IKEv2), how the negotiations are to be protected, and which hosts are allowed to negotiate keys. The absence of a key exchange policy is not considered an error, but without it, the IKE daemon is unable to provide dynamic key management.

A key exchange policy consists of an ordered list of key exchange rules. A key exchange rule consists of a set of security endpoints, and an action to be taken when the two security endpoints engage in an IKE phase 1 negotiation.
Optionally, a key exchange rule can contain a shared key known only to the two negotiating entities that are described in the rule. When an IKE negotiation is initiated, the current list of key exchange rules is searched for a match, based on four criteria:

- The identity of the local IKE peer, if known
- The identity of the remote IKE peer, if known
- The location (IP address) of the local IKE peer, if needed to distinguish it or if local identity is not known
- The location (IP address) of the remote IKE peer, if needed to distinguish it or if remote identity is not known

The following sample KeyExchangeRule block allows an IKE negotiation between IKE daemons at 9.2.2.2 and 9.4.4.4. A description of each line in the sample follows the sample.

```plaintext
1   KeyExchangeRule             ZoneB_KeyExRule1
2   {
3      LocalSecurityEndpoint
4      {
5         Identity              IpAddr 9.2.2.2
6         Location              9.2.2.2
7      }
8      RemoteSecurityEndpoint
9      {
10     Identity              X500dn CN=ZoneB Cert,T=IKE ServerB,OU=endicott,OU=ibm,C=US
11     Location              9.4.0.0/16
12     Calabel               CA4endicott
13     }
14   KeyExchangeActionRef     Gold-RSA
15   SharedKey                Ascii TheEagleHasLanded
16 }
```

<td>In the example, an IP address is used as the identity value.</td>
</tr>
<tr>
<td>6</td>
<td>The IP address of the local IKE peer.</td>
</tr>
<tr>
<td>7</td>
<td>A close brace (}) marks the end of the LocalSecurityEndpoint statement block.</td>
</tr>
</tbody>
</table>
The RemoteSecurityEndpoint statement identifies a remote security endpoint, or remote IKE peer. The RemoteSecurityEndpoint statement can also be used to define a related group of remote IKE peers by using wildcard values for identity and location.

The identity of the remote security endpoint that must match this rule. This can be one of five types:

- Fqdn
- IpAddr
- KeyID
- UserAtFqdn
- X500dn

In the example, an X.500 distinguished name is used as the identity value.

The IP subnetwork that defines a group of remote IKE peers.

Used only for digital signature peer authentication. Specifies the certificate authority that is advertised to the remote security endpoint as an acceptable authority. The value for this parameter must be the label of a certificate authority that is defined in RACF. The CaLabel parameter can be specified multiple times.

A close brace (}) marks the end of the RemoteSecurityEndpoint statement.

A reference to a key exchange action that has been defined elsewhere, in either the common or the stack-specific IP security configuration file, as follows:

```plaintext
KeyExchangeAction            Gold-RSA
{                           
    HowToInitiate              main
    HowToRespondIKEv1          main
    KeyExchangeOffer            
    {                          
        HowToEncrypt            3DES
        HowToAuthMsgs            SHA1
        HowToAuthPeers           RsaSignature
    }                          
}                            
```

The KeyExchangeAction statement specifies the detailed parameters that govern a phase 1 negotiation between these two security endpoints, such as who can begin the negotiation and what type of encryption is used.

An optional shared key used only for pre-shared key host authentication.

A close brace (}) marks the end of the KeyExchangeRule statement block.

**Example 1**

The following key exchange rule for an IKEv1 Aggressive-mode phase 1 negotiation uses pre-shared key authentication:

```plaintext
KeyExchangeRule              Admin_KeyExRule1
{                           
    LocalSecurityEndpointRef  Internal_IKED
    RemoteSecurityEndpointRef Admin_IKED
    KeyExchangeActionRef      Bronze-PSK
}                            
```
This rule defines the parameters for the IKEv1 phase 1 negotiation between two hosts that are identified by the security endpoints Internal_IKED and Admin_IKED (presumed to be defined elsewhere in the policy file). The specifics of the negotiation are covered by the Bronze-PSK action as follows:

KeyExchangeAction Bronze-PSK
{
  HowToInitiate Aggressive
  HowToRespondIKEv1 Aggressive

  KeyExchangeOffer
  {
    HowToEncrypt DES
    HowToAuthMsgs SHA1
    HowToAuthPeers PreSharedKey
  }
}

The optional SharedKey parameter is required only when the pre-shared key authentication method is used for the phase 1 negotiation.

**Example 2**

The following KeyExchangeRule statement for an IKEv1 Main-mode phase 1 negotiation uses digital signature authentication:

KeyExchangeRule ZoneA_KeyExRule1
{
  LocalSecurityEndpointRef Internal_IKED
  RemoteSecurityEndpointRef ZoneA_IKED
  KeyExchangeActionRef Silver-RSA
}

The referenced objects are presumed to be defined elsewhere in the policy file. This rule defines the parameters for the IKEv1 phase 1 negotiation between two hosts that are identified by the security endpoints Internal_IKED and ZoneA_IKED. The specifics of the negotiation are covered by the Silver-RSA action as follows:

KeyExchangeAction Silver-RSA
{
  HowToInitiate main
  HowToRespondIKEv1 main

  KeyExchangeOffer
  {
    HowToEncrypt DES
    HowToAuthMsgs SHA1
    HowToAuthPeers RsaSignature
  }
}

**Example 3**

The following key exchange rule for an IKEv2 phase 1 negotiation uses digital signature authentication:

KeyExchangeRule IKEv2_Example
{
  LocalSecurityEndpointRef Internal_IKED
  RemoteSecurityEndpointRef ZoneA_IKED
  KeyExchangeActionRef IKEv2-DigitalSignature
}

This rule defines the parameters for the IKEv2 phase 1 negotiation between two hosts that are identified by the security endpoints Internal_IKED and ZoneA_IKED (presumed to be defined elsewhere in the policy file). The specifics of the negotiation are covered by the IKEv2-DigitalSignature action as follows:

KeyExchangeAction IKEv2-DigitalSignature
{
  HowToInitiate IKEv2
  HowToAuthMe DigitalSignature
}
Key exchange rule order

“Example 1” on page 925 and “Example 2” on page 926 show individual key exchange rules. A complete key exchange policy contains any number of key exchange rules. Key exchange rules in a key exchange policy are searched in the order listed. In the process of an IKE negotiation, Policy Agent searches the list of active key exchange rules to locate a best match. It is possible for more than one key exchange rule to match a pending IKE negotiation. For this reason, the list of key exchange rules in the key exchange policy should be ordered from most specific to least specific in much the same way as the IP filter rules. If the key exchange policy contains key exchange rules with both unique and wildcard security endpoints, the most specific definitions should be placed higher in the list than the wildcard definitions.

For instance, there might be one key exchange rule governing a connection from an internal administrative machine, and another key exchange rule governing all other hosts on the internal network, as follows:

```
KeyExchangeRule Admin_KeyExRule1
{
  LocalSecurityEndpointRef  Internal_IKED
  RemoteSecurityEndpointRef Admin_IKED
  KeyExchangeActionRef      Bronze-PSK
  SharedKey                 Ascii TheEagleHasLanded
}
KeyExchangeRule ZoneA_KeyExRule1
{
  LocalSecurityEndpointRef  Internal_IKED
  RemoteSecurityEndpointRef ZoneA_IKED
  KeyExchangeActionRef      Silver-RSA
}
```

In this case, because the remote IKE peer that is defined by the remote security endpoint Admin_IKED matches both the Admin_KeyExRule1 and ZoneA_KeyExRule1 rules, the Admin_KeyExRule1 rule should be placed ahead of the ZoneA_KeyExRule1 rule in the key exchange policy as follows:

```
KeyExchangePolicy
{
  KeyExchangeRuleRef Admin_KeyExRule1
  KeyExchangeRuleRef ZoneA_KeyExRule1
  KeyExchangeRuleRef ZoneB_KeyExRule1
  KeyExchangeRuleRef ZoneC_KeyExRule1
}
```

Local dynamic VPN policy

A local dynamic VPN policy is required only if the IPSec negotiation is started through command-line activation using the `ipsec` command, or through automatic activation due to a local dynamic VPN policy update. IPSec negotiations can be initiated in one of four ways:

- On-demand
  The negotiation initiates when an outbound IP packet matches a filter rule with an ipsec action.
- Remotely
  The remote peer initiates the request, and the local IKE daemon responds.
- Command-line activation
  The `ipsec` command enables you to manually initiate an IPSec negotiation. (Not to be confused with manual tunnels, which do not use the IKE daemon at all.)
Autoactivation

The negotiation begins when either the stack or the IKE daemon initializes and both are active, or when the local dynamic VPN policy is updated.

A local dynamic VPN policy is required only in the last two cases.

A local dynamic VPN policy consists of an unordered list of local dynamic VPN rules. The negotiation for a phase 2 Security Association requires that the two communicating hosts agree on two data endpoints that the Security Association covers, the protocols the Security Association covers, and the ports that the Security Association covers. This information is then stored in the phase 2 Security Association, which is consulted each time relevant IPsec traffic needs to be encapsulated or decapsulated. The purpose of the local dynamic VPN rule is to define these requirements for each Security Association that is configured.

The following sample LocalDynVpnRule statement defines the parameters for the negotiation of a phase 2 Security Association for TN3270E Telnet server traffic between a server (9.1.1.1) and a client (9.4.4.100). A description of each line follows the sample.

```
1  LocalDynVpnRule      TelnetSA
2  {
3          LocalIP           9.1.1.1
4          RemoteIP          9.4.4.100
5          LocalDataPort     23
6          RemoteDataPort    0
7          Protocol          tcp
8          Autoactivate      yes
9  }                 
```

<table>

<td>The local address of IP traffic that this Security Association is to protect. The address can be either a single address or a range of addresses. However, if the address is not a single address, this Security Association must be negotiated for tunnel mode.</td>
</tr>
<tr>
<td>4</td>
<td>The remote address of IP traffic that this Security Association is to protect. The address can be either a single address or a range of addresses. However, if the address is not a single address, this Security Association must be negotiated for tunnel mode.</td>
</tr>
<tr>
<td>5</td>
<td>The local ports for IP traffic that this Security Association is to protect. The port must be either a single port or all ports. A range of ports is not allowed. A value of 0 indicates all ports.</td>
</tr>
<tr>
<td>6</td>
<td>The remote ports for IP traffic that this Security Association is to protect. The port must be either a single port or all ports. A range of ports is not allowed. A value of 0 indicates all ports.</td>
</tr>
<tr>
<td>7</td>
<td>The protocol that this Security Association is to protect. This value can be numeric. It must define a single protocol or all protocols.</td>
</tr>
<tr>
<td>8</td>
<td>Indicates that this Security Association is to be activated when the stack and IKE daemon are active. No user intervention is required.</td>
</tr>
<tr>
<td>9</td>
<td>A close brace (}) marks the end of the LocalDynVpnRule statement block.</td>
</tr>
</tbody>
</table>

An on-demand Security Association does not require a local dynamic VPN rule definition. All of the parameters for the negotiation of an on-demand phase 2 Security Association can be inferred from one of two places, either the packet that began the on-demand activation or the filter rule on which the packet
matched. The packet always provides a single value for address, protocol, port, type, and code. The filter rule, however, can allow for a range of values for IP address, protocol, port, type, or code. The granularity setting of the IpLocalStartAction statement determines whether the information is taken from the packet or from the matching filter rule. For more information regarding the IpLocalStartAction statement, see z/OS Communications Server: IP Configuration Reference.

Security Associations can be defined as wide or narrow with respect to IP addresses or ports and protocols. If a Security Association is wide with respect to IP address, the same Security Association is used to protect data between multiple endpoints. If a Security Association is wide with respect to ports and protocols, the same Security Association is used to protect multiple traffic types. Conversely, a narrowly defined Security Association can be used to protect specific data endpoints (based on IP address) or specific traffic types (based on commonly used ports and protocols for network services). Security Associations negotiated with IKEv2 can also be narrow with respect to types and codes.

**Example 1 - wide Security Association**

The following rule allows any type of traffic to flow between PublicServerAddressA1 and SubnetC using the same Security Association. PublicServerAddressA1 and SubnetC can be defined in either the common or the stack-specific IP security configuration file. The AutoActivate parameter causes the IKE negotiation to initiate when the stack or IKE initializes.

```
LocalDynVpnRule ZoneC_VPN-All-traffic
{}
  LocalIpRef PublicServerAddressA1
  RemoteIpSetRef SubnetC
  Protocol all
  AutoActivate yes
{}
IpAddr PublicServerAddressA1
{
  Addr 9.3.3.3
}
IpAddrSet SubnetC
{
  Prefix 9.6.0.0/16
}
```

**Example 2 - narrow Security Association**

If narrow Security Associations are used for IPSec-protected FTP traffic, two VPN definitions are required, one for the data connection and one for the control connection. The following rules are from the server's perspective. The FTP client connecting from BranchOfficeAddressC1 to the PublicServerAddressA1 ports 20 and 21 uses the respective ZoneC FTP VPNs.

```
LocalDynVpnRule ZoneC_VPN-FTP-Data
{
  LocalIpRef PublicServerAddressA1
  RemoteIpRef BranchOfficeAddressC1
  LocalDataPort 20
  RemoteDataPort 0
  Protocol tcp
}
LocalDynVpnRule ZoneC_VPN-FTP-Control
{
  LocalIpRef PublicServerAddressA1
  RemoteIpRef BranchOfficeAddressC1
  LocalDataPort 21
  RemoteDataPort 0
  Protocol tcp
}
IpAddr PublicServerAddressA1
{
  Addr 9.3.3.3
}
IpAddr BranchOfficeAddressC1
```
Quick start using IP filtering and IPSec host-to-host

The following sample shows a complete IP security policy allowing connections from a secure server (9.1.1.1) to an administrative machine (9.1.1.2) on an internal network. It represents the absolute minimum number of items that need to be configured for the IKED to provide IPSec protection with dynamic key management between two hosts.

Tip: You can modify the quick start sample for IPv6 by replacing all IPv4 addresses with IPv6 addresses.

This IP security policy allows IKE negotiations in the clear (UDP, port 500 traffic), while authenticating and encrypting all other traffic using the ESP IPSec protocol. The policy relies almost exclusively on the z/OS IP security policy defaults, including MD5 and DES for the phase 1 Security Association and ESP/MD5 ESP/DES for the phase 2 Security Association. For a complete description of IP security policy configuration statements and their defaults, see z/OS Communications Server: IP Configuration Reference.

```
#-------------------------------------------------------
# Quick-Start IP Security policy
#-------------------------------------------------------
IpFilterPolicy
{
    PreDecap                  off
    FilterLogging            on
    AllowOnDemand            yes
    IpFilterRule             QuickStartRule1
    {
        IpSourceAddr       9.1.1.1
        IpDestAddr         9.1.1.2
        IpService
        {
            SourcePortRange  500
            DestinationPortRange  500
            Protocol           udp
            Direction          bidirectional
            Routing            local
        }
        IpGenericFilterActionRef permit
    }
    IpFilterRule             QuickStartRule2
    {
        IpSourceAddr       9.1.1.1
        IpDestAddr         9.1.1.2
        IpService
        {
            Direction          bidirectional
            Routing            local
        }
        IpGenericFilterActionRef ipsec
        IpDynVpnActionRef   TransportMode
    }
}
KeyExchangePolicy
{
    KeyExchangeRule          QuickStart_KeyExRule
    {
        LocalSecurityEndpoint
        {
            Identity           IpAddr 9.1.1.1
            Location           9.1.1.1
        }
        RemoteSecurityEndpoint
        {
            Identity           IpAddr 9.1.1.2
            Location           9.1.1.2
        }
        KeyExchangeActionRef QuickStart_KeyExAction
        SharedKey            Ascii TheEagleHasLanded
    }
}
```
For all IKE negotiations, there must be a corresponding and consistent configuration on the remote host. In this case, if the remote system is running with z/OS IP security, the corresponding policy for the remote system can be generated merely by transposing all instances of local and remote IP addresses.

### Displaying filters, rules, and actions

To display the filter rules for the quick start policy after they have been installed in the stack, enter the following UNIX System Services command:

```plaintext
ipsec -f display -r detail -c current
```

```plaintext

*******************************************************************************
Each IP service in the example uses the bidirectional keyword. Therefore, two rules are created for each IP service, one outbound and one inbound. When the IP filter rules are expanded in this way, the specific filter rules are distinguished from each other by a unique numeric value in the FilterNameExtension field.

Note that the last four deny rules are not explicitly coded in the IP security configuration file, but are added by the system in keeping with a default-deny policy.

For more information on displaying active filters with the `ipsec` command, see “Displaying active filters with the ipsec command” on page 1020.

To view the quick start filter rules using the `pasearch` command, issue the following command:

```
pasearch -v f
```

TCP/IP pasearch CS V1R12    Image Name: TCPCS

**Activating the quick start Security Association**

The quick start policy enables on-demand activation of a Security Association between the two endpoints. The Security Association is a wide Security Association allowing any type of traffic. Therefore, it can be
activated by sending any type of traffic from the local host at 9.1.1.1 to the remote host at 9.1.1.2 as follows:

```
ping -s 9.1.1.1 9.1.1.2
CS V1R12: Pinging host 9.1.1.2
sendto(): EDC5111I Permission denied. (errno2=0x74420291)
```

Because the Security Association does not exist, the initial `ping` attempt fails. After the negotiation for the Security Association has activated and the Security Association is established, a subsequent `ping` attempt succeeds as follows:

```
ping -s 9.1.1.1 9.1.1.2
CS V1R12: Pinging host 9.1.1.2
Ping #1 response took 0.001 seconds.
```

**Displaying the quick start Security Associations**

Use the `ipsec` command to display both the phase 1 and phase 2 Security Associations between 9.1.1.1 and 9.1.1.2. The following command displays the phase 1 Security Associations:

```
ipsec -k display -r detail
CS V1R12 ipsec Stack Name: TCPCS Tue Feb 16 10:38:12 2010
Primary: IKE tunnel Function: Display Format: Detail
Source: IKED Scope: Current TotAvail: n/a
TunnelID: K1
Generation: 1
IKEVersion: 1.0

Steps for configuring IP security policy

These steps are used to configure the specific security models.

Procedure

Perform the following steps to configure IP security policy.
1. Determine the number of zones to be protected. A zone typically equates to a subnetwork that is reachable by the host server, but can be any group of IP addresses that are conceptually related. The internal network can be defined in one or several zones, while any external network or group of networks can be placed in separate zones. Each zone should have meaning related to the site’s security policy. If a zone maps to a physical interface, optionally assign a security class to all interfaces in that zone.

2. For each zone, determine what services are allowed and define an IpService statement for each wanted service. Services are defined by the protocols and well-known ports that they use.

3. Determine the data endpoints to be protected. Typically, this is both a local and remote IP address, or subnetwork.

4. Determine what level of security is needed between each set of data endpoints. The level of security can be deny, permit, or ipsec.

5. Configure an IpGenericFilterAction statement for the level of security that is required (permit, deny, ipsec), including whether the connection should be logged.

6. If IPSec is required between any two endpoints:
   a) Configure a KeyExchangePolicy statement that defines the parameters of the phase 1 negotiation:
      1) Determine the required type and strength of protection for the phase 1 Security Association.
      2) Decide what type of peer authentication will be used:
         • If digital signature, set up RACF certificates and certificate authority information.
         • If pre-shared key, create a secret key that is known to both peers.
      3) Decide whether NAT traversal will be allowed. If the network topology contains one or more NAT devices that must be traversed by the phase 1 Security Association, NAT traversal should be allowed.
      4) Configure a KeyExchangeOffer statement.
      5) Determine negotiation mode, IKEv1 Main, IKEv1 Aggressive, or IKEv2.
      6) Configure a KeyExchangeAction statement.
      8) Configure a KeyExchangeRule statement that includes the two endpoints and the key exchange action.
      9) Include the KeyExchangeRule statement in the KeyExchangePolicy statement block.
   b) Configure an IpDynVpnAction statement that defines the control of the phase 2 negotiation:
      1) Determine the required type and strength of IPSec protection for the phase 2 Security Association.
      2) Determine whether tunnel or transport mode is required. For an IKEv2 negotiation, the appropriate mode is chosen based on topology.
      3) Configure an IpDataOffer statement that defines the parameters of the phase 2 negotiation.
      4) Determine which peer should be allowed to initiate the negotiation.
   c) Decide how the Security Association is to be activated:
      1) Configure an optional LocalDynVpnPolicy statement, if command-line activated or autoactivated.
      2) Configure an optional IpLocalStartAction statement, if the Security Association is to be activated locally (that is, on-demand, command-line, or autoactivation) and one of the security endpoints is acting as a security gateway (that is, not a host-to-host Security Association). Include a reference to the IpLocalStartAction statement in the IP filter rule.
      3) Either create an IpFilterRule statement that allows IPSec traffic (AH and ESP), or set the global PreDecap parameter of the IpFilterPolicy statement to off.

7. Define an IpFilterRule statement for each set of data endpoints.
The rule should include the services that are allowed (one IpService statement for each allowed service), and the level of security that is required (a reference to the IpGenericFilterAction statement). If IPSec is required, create an IpFilterRule statement that allows IKE traffic (UDP, port 500). If NAT traversal is allowed, create an IpFilterRule statement that allows IKE UDP traffic on port 4500.

**Rule:** To allow IKE negotiations for Security Associations, IKE traffic (port 500, and optionally port 4500 for NAT traversal) must be permitted in the clear.

8. Define an IpFilterGroup statement for each zone and include the IpFilterRule statements that belong to that zone.

10. Include all configured statements in the IP security configuration file.

For more information, see:

- “Steps for configuring local IP security policy using only a common IP security configuration file” on page 914
- “Steps for configuring remote IP security policy using only a common IP security configuration file” on page 915
- “Steps for configuring local IP security policy using only a stack-specific IP security configuration file” on page 916
- “Steps for configuring remote IP security policy using only a stack-specific IP security configuration file” on page 916
- “Steps for configuring local IP security policy using both a stack-specific file and a common file” on page 917
- “Steps for configuring remote IP security policy using both a stack-specific file and a common file” on page 918

**Results**

For examples of the use of these steps, see “Configuring specific security models” on page 946.

**Configuring specific security models**

Setting up IP security configuration files can be a complex task, as there are many powerful features, options, and controls. However, after the security needs of the business are identified, implementing an IP security policy becomes a matter of translating the requirements to a Policy Agent configuration file.

The choice of protection model primarily depends on the network topology. Although it is perfectly permissible to follow a single model when configuring IP security policy, the z/OS IP security function enables any number of models to be installed concurrently. Commonly, one set of rules governs internal network traffic, another protects traffic from connected networks, and a third provides security for traffic that is routed over the Internet. The following scenarios presume that you are configuring a secure server that is a multihomed host that is connected to an internal, an external, and a wide-area network that traverses the Internet. The configuration guidelines that are presented in the following subtopics are based on three business models:

- **Trusted internal network (permit, deny)**

  In the trusted internal network model, the server is protecting traffic that originates from hosts inside a privately controlled network. IP packets on the internal network are not generally subject to the stringent restrictions that are placed on traffic that is generated from outside the business. This model is usually more tolerant, given that users inside the company need access to internal network resources and services, such as the web, FTP, and Telnet.

- **Partner company (permit, deny, strong IPSec protection)**

  The partner company model consists of two interconnected networks, with the server protecting traffic that originates from hosts outside the internal network. Typically, two separate networks are physically connected to the z/OS server. Because the traffic is not restricted to internal hosts, security is usually...
somewhat tighter than in the trusted internal network model. Each partner company has no physical control over the machine of the other partner company. The services that are provided are determined by the needs of the business, but typically include many of the same services that are provided to the internal network, such as access to a web server, FTP, and Telnet. Though many services might be allowed between partner companies, the need for confidentiality and authentication of data is more stringent than in the trusted internal network model, because there is little to no control over the other network. IPSec is often specified to authenticate and optionally encrypt data that flows between the two networks.

- Branch office (permit, deny, strong tunnel-mode IPSec protection)

The branch office model consists of two networks whose IP connectivity relies on the Internet. The server is protecting traffic that originates from hosts outside the internal network, which at some point is routed over the Internet. Because there is no control over any data that traverses the Internet, the need for security is greatest in this model. The services that are provided are based on business need, but typically include a subset of what is available internally. All traffic that traverses the Internet carrying vital information should be secured using some form of authentication and encryption.

Figure 117 on page 947 shows a sample network for all three security models.

Figure 117. Security model network

The following subtopics describe how to configure these models using the steps described in “Steps for configuring IP security policy” on page 944. The policy examples assume that a default-deny policy is in place. Any traffic not explicitly permitted is blocked.

Steps for configuring the trusted internal network model (simple IP filtering)
In the trusted internal network model, the server is protecting traffic that originates from hosts inside a privately controlled network.

Before you begin
The following statements, concepts, and files are covered in the discussion of this model:
- IpFilterRule
- IpService
Figure 118 on page 948 shows the trusted internal network portion of the security model network.

**Internal (A) 9.1.1.0/24**

For this example, assume that the following requirements must be met to control traffic on the internal network:

- Give FTP access to an administrator from a host inside the internal network (9.1.1.2) to the secure server (9.1.1.1). Log any traffic that matches this traffic pattern.
- Allow web access (HTTP, port 80) to the secure server from any host on the internal network (9.1.1.0/24). Do not log any traffic that matches this traffic pattern.
- Deny all other traffic.

**Procedure**

Perform the following steps to meet these requirements and configure the trusted internal network model.

1. Determine the number of zones to be protected.
   - There is only one zone for this example, the internal network 9.1.1.0/24.
2. For each zone, determine what services are allowed and define an IpService block for each wanted service. Optionally, assign a security class to all interfaces in each zone.
   - There are two services stated in the example requirements, HTTP and FTP. The traffic is local to this host and, therefore, the routing is designated as local. No forwarding of these services is allowed.
Because the entire internal network is defined in one zone, you can define a unique security class for the interface with address 9.1.1.1. For this example, the SECCLASS parameter of all internal network interfaces is assigned the arbitrary value of 1, which can be interpreted to mean a trusted network. If you specify the SecurityClass parameter in the IpService block, the related interface must be assigned the same value on the SECCLASS parameter of the LINK or INTERFACE statement in the TCP/IP profile. In this example, the traffic is allowed only over an interface with a SECCLASS parameter value of 1, presumed to be the interface connected to the internal network.

```
IpService
{
  SourcePortRange       80
  DestinationPortRange  1024 65535
  Protocol              tcp
  Direction             bidirectional InboundConnect
  Routing               local
  SecurityClass         1
}
```

Because normal FTP uses two well-known ports, two services are required, one for the control connection and one for the data connection:

```
IpService
{
  SourcePortRange       21
  DestinationPortRange  1024 65535
  Protocol              tcp
  Direction             bidirectional InboundConnect
  Routing               local
  SecurityClass         1
}
IpService
{
  SourcePortRange       20
  DestinationPortRange  1024 65535
  Protocol              tcp
  Direction             bidirectional OutboundConnect
  Routing               local
  SecurityClass         1
}
```

The InboundConnect keyword is used for services that are not allowed to initiate a TCP connection. The OutboundConnect keyword is used for services that are not allowed to receive a TCP connection request. If neither keyword is specified, either side can initiate a TCP connection.

3. Determine the data endpoints to be protected.

There are two sets of data endpoints to be protected in this example, representing the connection from the administrative machine, and all the other hosts on the subnetwork:

```
Local  Address of secure server: 9.1.1.1
Remote Address of administrative machine: 9.1.1.2

Local  Address of secure server: 9.1.1.1
Remote Address of all hosts on internal network: 9.1.1.0/24
```

4. Determine what level of security is needed between each set of data endpoints.

In this example, only permit is required. Therefore, no IPSec information is needed. Because z/OS IP security policy implicitly provides a default-deny policy, all other traffic is denied.

5. Configure an IpGenericFilterAction statement for the level of security (permit, deny, ipsec) that is required, including whether the connection is logged.

Because the example requirement is to permit two types of traffic with different logging requirements, two actions are needed as follows:

```
IpGenericFilterAction    permit-log
{
  IpFilterAction       permit
  IpFilterLogging       yes
}
```
6. If IPSec is required between any two endpoints, configure a KeyExchangePolicy statement that defines the parameters of the phase 1 negotiation, configure an IpDynVpnAction statement that defines the control of the phase 2 negotiation, and decide how the Security Association is to be activated.

IPSec is not required in this example. If there was sensitive data flowing through the internal network that needed to be confidential, IPSec could be specified to encrypt some IP packets, thereby effectively securing information that travels between two hosts on the internal network.

7. Define an IpFilterRule block for each set of data endpoints.

Each rule should include the services that are allowed (one IpService statement for each allowed service), and the level of security that is required (a reference to the IpGenericFilterAction statement). If IPSec is required, create an IpFilterRule statement that allows IKE traffic (UDP, port 500). If NAT traversal is allowed, create an IpFilterRule statement that allows IKE UDP traffic on port 4500.

In this example, the source address refers to an address on the secure host. The destination address refers to remote hosts. The IpService statements are the ones defined in step “2” on page 948. Note that the IpGenericFilterAction statement must reference a previously defined action.

```verbatim
IpGenericFilterAction    permit-nolog
{                     
  IpFilterAction       permit
  IpFilterLogging      no
}

IpFilterRule             AdminFTP
{                     
  IpSourceAddr        9.1.1.1
  IpDestAddr          9.1.1.2
  IpService
  {                     
    SourcePortRange    21
    DestinationPortRange 1024 65535
    Protocol            tcp
    Direction           bidirectional InboundConnect
    Routing             local
    SecurityClass       1
  }
  IpService
  {                     
    SourcePortRange    20
    DestinationPortRange 1024 65535
    Protocol            tcp
    Direction           bidirectional OutboundConnect
    Routing             local
    SecurityClass       1
  }
  IpGenericFilterActionRef  permit-log
}

IpFilterRule             InternalNetWeb
{                     
  IpSourceAddr        9.1.1.1
  IpDestAddrSet       9.1.1.0/24
  IpService
  {                     
    SourcePortRange    80
    DestinationPortRange 1024 65535
    Protocol            tcp
    Direction           bidirectional InboundConnect
    Routing             local
    SecurityClass       1
  }
  IpGenericFilterActionRef  permit-nolog
}

IpGenericFilterAction    permit-log
{                     
  IpFilterAction       permit
  IpFilterLogging      yes
}

IpGenericFilterAction    permit-nolog
```
Because IPSec is not required in this example, no filters for IKE traffic are needed.

8. Include the IpFilterRule statements in the IpFilterPolicy block.

The IP filter rules and their relative placement within the IpFilterPolicy block should be from most specific to least specific. Because the AdminFTP rule controls traffic from a specific host, it should be placed before the InternalNetWeb rule. Note that to enable logging of the individual rules, filter logging must be enabled at the global level of the IP filter policy with the FilterLogging parameter.

```
IpFilterPolicy
{
  FilterLogging on
  IpFilterRule AdminFTP
  {
    IpSourceAddr 9.1.1.1
    IpDestAddr 9.1.1.2
    IpService
    {
      SourcePortRange 21
      DestinationPortRange 1024 65535
      Protocol tcp
      Direction bidirectional InboundConnect
      Routing local
      SecurityClass 1
    }
  }
  IpService
  {
    SourcePortRange 20
    DestinationPortRange 1024 65535
    Protocol tcp
    Direction bidirectional OutboundConnect
    Routing local
    SecurityClass 1
  }
  IpGenericFilterActionRef permit-log
}
IpFilterRule InternalNetWeb
{
  IpSourceAddr 9.1.1.1
  IpDestAddrSet 9.1.1.0/24
  IpService WebServer
  {
    SourcePortRange 80
    DestinationPortRange 1024 65535
    Protocol tcp
    Direction bidirectional InboundConnect
    Routing local
    SecurityClass 1
  }
  IpGenericFilterActionRef permit-nolog
}
```

9. Include all configured statements in the stack-specific IP security configuration file.

The IpFilterPolicy statement and the IpGenericFilterAction statements are placed in the file in no particular order, although the file is easier to read if logically related items are placed close together. For further ease of reading and maintenance, document the file with comments, which begin with the number sign (#).

The completed stack-specific IP security configuration file for the internal network with two filter rules follows:

```
# IP Security policy for Secure Server
###############################
# IpFilterPolicy block #
###############################
IpFilterPolicy
{
  FilterLogging on
  #Allow admin FTP; log traffic
```
10. Define an IP filter group for each zone, and include the IP filter rules that belong to that zone.

In step “9” on page 951, both IpFilterRule statements include a reference to statements defined outside of the IpFilterRule block, the IpGenericFilterAction statements. Some other information, such as IP addresses and services, is undoubtedly to be needed more than once. Changing these occurrences to reference objects eliminates repeated typing of the same information and adds clarity to the configuration file. To take advantage of references, the reusable statements must be given a name.

- Single IP addresses are defined by the IpAddr statement, which contains one parameter, Addr:

```plaintext
IpAddr                    InternalNetServerAddress
{                          
  Addr                    9.1.1.1
}
IpAddr                    InternalNetAdminAddress
{                          
  Addr                    9.1.1.2
}
```
• Ranges or subnetworks are defined by the IpAddrSet statement, which contains either a Range or Prefix attribute:

```
IpAddrSet InternalNet
{  Prefix       9.1.1.0/24
}
```

• To be referenced, each IpService statement needs a name:

```
IpService      WebServer
{  SourcePortRange       80
  DestinationPortRange   1024 65535
  Protocol              tcp
  Direction             bidirectional InboundConnect
  Routing               local
  SecurityClass         1
}

IpService     FTPServer-Control
{  SourcePortRange       21
  DestinationPortRange   1024 65535
  Protocol              tcp
  Direction             bidirectional InboundConnect
  Routing               local
  SecurityClass         1
}

IpService     FTPServer-Data
{  SourcePortRange       20
  DestinationPortRange   1024 65535
  Protocol              tcp
  Direction             bidirectional OutboundConnect
  Routing               local
  SecurityClass         1
}
```

• FTP is composed of two individual services, and both can be condensed into an IpServiceGroup that references the two FTP services:

```
IpServiceGroup    FTPServer
{  IpServiceRef   FTPServer-Control
  IpServiceRef   FTPServer-Data
}
```

• The IP filter rules can be grouped as well. Because the filter rules that apply to the internal network naturally relate to each other in the sense that they apply to the same security zone, they can be combined into an IpFilterGroup statement:

```
IpFilterGroup     InternalNetZoneA
{  IpFilterRef    AdminFTP
  IpFilterRef    InternalNetWeb
}
```

Notice that just as the list of IpFilterRule statements in the IpFilterPolicy block is ordered, the list of IpFilterRef statements in the IpFilterGroup block is also ordered. The InternalNetWeb rule applies to all of the IP addresses in the network, including the administrative machine. However, the AdminFTP rule is more specific because it applies only to a specific address within that network. The more specific rule is placed first in the list.

Now that all reusable statements have been identified and separately defined, they can be incorporated into any statement that requires that reusable statement type. The modified stack-specific IP security configuration file using references follows. Note that by adding names and organizing related statements, the purpose of the IpFilterPolicy statement is clarified.

```
# IP Security policy for Secure Server
##########################
# IpFilterPolicy block  #
```

IP security 953
IpFilterPolicy
{
  FilterLogging on
  IpFilterGroupRef InternalNetZoneA
}

IpFilterGroup InternalNetZoneA
{
  IpFilterRuleRef AdminFTP
  IpFilterRuleRef InternalNetWeb
}

IpFilterRule AdminFTP
{
  IpSourceAddrRef InternalNetServerAddress
  IpDestAddrRef InternalNetAdminAddress
  IpServiceGroupRef FTPServer
  IpGenericFilterActionRef permit-log
}

IpFilterRule InternalNetWeb
{
  IpSourceAddrRef InternalNetServerAddress
  IpDestAddrSetRef InternalNet
  IpServiceRef WebServer
  IpGenericFilterActionRef permit-nolog
}

IpGenericFilterAction permit-log
{
  IpFilterAction permit
  IpFilterLogging yes
}

IpGenericFilterAction permit-nolog
{
  IpFilterAction permit
  IpFilterLogging no
}

IpService WebServer
{
  SourcePortRange 80
  DestinationPortRange 1024 65535
  Protocol tcp
  Direction bidirectional InboundConnect
  Routing local
  SecurityClass 1
}

IpService FTPServer-Control
{
  SourcePortRange 21
  DestinationPortRange 1024 65535
  Protocol tcp
  Direction bidirectional InboundConnect
  Routing local
  SecurityClass 1
}

IpService FTPServer-Data
{
  SourcePortRange 20
  DestinationPortRange 1024 65535
}
This stack-specific IP security configuration file gives FTP access to the administrator and web access to everyone in the internal network. By relying heavily on the abstracted use of references, the policy is not only more self-explanatory, but changes to any referenced object are propagated to any statement that references it. So, if the IP address of the administrative machine or internal subnetwork changes, you merely have to make one change to an IpAddr or IpAddrSet statement, rather than modify a large number of instances in multiple rules.

**Using a common IP security configuration file for reusable statements**

The stack-specific IP security configuration file should be tailored to the specific stack to which it belongs. However, as the policy files for IP security are being constructed, a large number of statements can be reused. Reusable statements can be placed in a common file, which is available to all stacks. Statements in the common IP security configuration file are read by all stacks on the system, providing a convenient way to store common definitions that they can all share. If you are operating in a sysplex, you can also place a common IP security configuration file on shared DASD or in a shared z/OS File System directory so that stacks in a multiple sysplex image have access to the same common configuration file.

Assuming that all statements that might be used later are placed in a common IP security configuration file, the stack-specific IP security configuration file from step 10 now reads as follows:
#Allow admin FTP; log traffic
IpFilterRule AdminFTP
{
  IpSourceAddrRef InternalNetServerAddress
  IpDestAddrRef InternalNetAdminAddress
  IpServiceGroupRef FTPServer
  IpGenericFilterActionRef permit-log
}

#Allow LAN Web traffic; don't log
IpFilterRule InternalNetWeb
{
  IpSourceAddrRef InternalNetServerAddress
  IpDestAddrSetRef InternalNet
  IpServiceRef WebServer
  IpGenericFilterActionRef permit-nolog
}

This stack-specific IP security configuration file references the following reusable statements:

- InternalNetServerAddress
- InternalNetAdminAddress
- InternalNet
- FTPServer
- FTPServer-Control
- FTPServer-Data
- permit-log
- permit-nolog
- WebServer

IpFilterRule statements can also be placed in the common IP security configuration file, because some IP filter rules apply to all addresses. If certain IpFilterRule statements are to apply globally to all stacks on the system, they can go into the common file. Use a value of all for the IpSourceAddr and IpDestAddr attributes. For instance, if all stacks on a z/OS system need rules permitting dynamic routing traffic (OSPF or RIP, for example), the statements that define this type of traffic can be placed in the common file and referenced in the stack-specific file:

```bash
IpFilterRule AllowOmprouteLocalNolog
{
  IpSourceAddr all
  IpDestAddr all
  IpServiceGroupRef Omproute-local
  IpGenericFilterActionRef Permit-nolog
}

IpServiceGroup Omproute-local
{
  IpServiceRef OSPF-local
  IpServiceRef RIP-local
}

IpService OSPF-local
{
  Protocol OSPF
  Direction bidirectional
  Routing local
}

IpService RIP-local
{
  Protocol UDP
  SourcePortRange 520
  DestinationPortRange 520
  Direction bidirectional
  Routing local
}
```
With these definitions in the common IP security configuration file, any stack needing global permission to send and receive routing information merely needs to include the following statement in the IpFilterPolicy block of its stack-specific IP security configuration file:

```
IpFilterRuleRef  AllowOmprouteLocalNolog
```

**Steps for configuring the partner company model (host-to-host with IPSec)**

The partner company model consists of two interconnected networks, with the server protecting traffic that originates from hosts outside the internal network.

**Before you begin**

The following statements and concepts are covered in the discussion of this model:

- Dynamic host-to-host IKE negotiations
- Key exchange rules
- Local and remote security endpoints
- Use of wildcards in Location and Identity
- IpLocalStartAction
- Granularity
- RSA signature peer authentication
- Certificates and certificate authorities
- On-demand activation
- Remote activation

Figure 119 on page 957 shows the partner company portion of the security model network.

The partner company model is similar to that of the internal network, but an increased need for security means that a greater number of connections rely on data authentication and encryption. Although some services are allowed in the clear, sensitive data needs IPSec protection. To apply IPSec to a connection, the traffic that flows over that connection must match an IP filter rule that has an ipsec action.

For this example, assume you must meet the following requirements to allow network communications from a partner company in an untrusted zone B over a connected network (9.4.0.0/16) to a public IP address (9.2.2.2) on this host:

- Allow IKE traffic from untrusted zone B to this host.
- Allow secure FTP traffic (using TLS/SSL) from untrusted zone B to a secure FTP server running on this host.

Secure FTP has its own security mechanism. Although IPSec can be used together with TLS/SSL, using both adds processing expense. For this example, secure FTP is allowed without IPSec protection.
• Allow Enterprise Extender (EE) traffic from untrusted zone B to an EE service running on this host using a dynamic IPSec tunnel with strong encryption and authentication.

Because there is no encryption mechanism used in this example for EE, IPSec provides the secure service.

• Allow FTP traffic from untrusted zone B to an FTP server running on this host using a dynamic IPSec tunnel with strong AH authentication.

• The dynamic IPSec tunnel for EE comes up when outbound EE traffic is detected (on-demand activation).

• A dynamic IPSec tunnel for normal FTP control activates for each remote host that initiates an FTP connection (remote activation).

• A dynamic IPSec tunnel for normal FTP data activates for each outbound data connection to a remote host (local activation).

• Peers authenticate themselves using the RSA signature method.

Procedure

Perform the following steps to meet these requirements and configure the partner company model.

1. For each zone, determine what services are allowed:

   • IKE traffic
   • Normal FTP traffic
   • Secure FTP traffic
   • Enterprise Extender traffic

2. Define an IpService statement for each wanted service.

   • IKE uses UDP, port 500 for message exchanges:

     ```
     IpService IKE-local {
       SourcePortRange 500
       DestinationPortRange 500
       Protocol UDP
       Direction bidirectional
       Routing local
       SecurityClass 0
     }
     ```

   • For normal FTP traffic, allow inbound connections but do not allow outbound connection requests, other than data. Two services are required, one for the control connection and one for the data connection:

     ```
     IpService FTPServer-Control {
       SourcePortRange 21
       DestinationPortRange 1024 65535
       Protocol tcp
       Direction bidirectional InboundConnect
       Routing local
       SecurityClass 0
     }
     IpService FTPServer-Data {
       SourcePortRange 20
       DestinationPortRange 1024 65535
       Protocol tcp
       Direction bidirectional OutboundConnect
       Routing local
       SecurityClass 0
     }
     ```
• For secure FTP traffic, allow inbound connections but do not allow outbound connection requests, other than data. Two services are required, one for the control connection and one for the data connection.

```
IpService SecureFTPServer-Control
{
  SourcePortRange 990
  DestinationPortRange 1024 65535
  Protocol tcp
  Direction bidirectional InboundConnect
  Routing local
  SecurityClass 0
}
IpService SecureFTPServer-Data
{
  SourcePortRange 989
  DestinationPortRange 1024 65535
  Protocol tcp
  Direction bidirectional OutboundConnect
  Routing local
  SecurityClass 0
}
```

• For Enterprise Extender traffic, allow both inbound and outbound traffic:

```
IpService Enterprise-Extender
{
  SourcePortRange 12000 12004
  DestinationPortRange 12000 12004
  Protocol UDP
  Direction bidirectional
  Routing local
  SecurityClass 0
}
```

IP services can be grouped together for convenience, flexibility, and reuse of configuration. Any IP filter rule that includes an IP service group will be expanded to include all of the services from that group. The following IP service groups include the IP services that define the FTPServer and the SecureFTPServer:

```
IpServiceGroup FTPServer
{
  IpServiceRef FTPServer-Control
  IpServiceRef FTPServer-Data
}
IpServiceGroup SecureFTPServer
{
  IpServiceRef SecureFTPServer-Control
  IpServiceRef SecureFTPServer-Data
}
```

3. Determine the data endpoints to be protected.

   In this example, the local data endpoint is the public address of the server, and the remote data endpoint is the entire subnetwork in zone B:

   Local public IP address: 9.2.2.2
   Remote subnet: 9.4.0.0/16

4. Determine what level of security is needed between each set of data endpoints:

   IKE traffic - permit
   Secure FTP traffic - permit
   EE traffic - IPSec encryption and authentication
   FTP traffic - IPSec authentication

5. Configure an IpGenericFilterAction statement for the level of security that is required.

   The requirements stated that IKE and secure FTP should be allowed, and that EE and normal FTP traffic required IPSec protection. Notice that the parameters of the IpGenericFilterAction statement
include ipsec as well as permit and deny. Because no logging requirements were specified, two actions are needed, permit and ipsec:

```
IpGenericFilterAction    permit-nolog
{   IpFilterAction       permit
IpFilterLogging         no
}
IpGenericFilterAction    ipsec-nolog
{   IpFilterAction       ipsec
IpFilterLogging         no
}
```

6. If IPSec is required between any two endpoints, take the following actions:

   a) Configure a key exchange policy that defines the parameters of the phase 1 negotiation as follows:

      1) Determine the required type and strength of protection for the phase 1 Security Association. Phase 1 Security Associations must use both authentication and encryption. Because strong encryption was specified for phase 2, use strong encryption for phase 1:

         ```
         Authentication, SHA1 algorithm
         Encryption, 3DES algorithm
         DHGroup, Diffie-Hellman Group2
         ```

         **Tip:** The greater the Diffie-Hellman group specified, the greater the protection provided.

      2) Decide what type of peer authentication is used:

         ```
         RSA signature
         ```

         Because the remote data endpoint represents multiple hosts in this example, RSA signature is used. RSA signature authentication provides greater flexibility, scalability, and security than pre-shared key authentication. Because there are potentially multiple remote peers in the partner company's subnet, RSA signature is a reasonable choice.

         The use of RSA signature requires setup of RACF certificates and certificate authority information. Both IKE peers need access to a key ring with at least one X.509 digital certificate to identify itself. To set up the IKE daemon for certificates, see Appendix E, "Steps for preparing to run IP security," on page 1331. The site should decide what certificate authorities are recognized. A certificate authority can be an outside commercial entity, or it can be defined locally in RACF. For information about installing certificate authorities in RACF, see z/OS Security Server RACF Security Administrator's Guide.

         In this example, the IKEv1 protocol is used and the IKE daemon is using the native certificate service. A certificate authority with label CA4PartnerCompany is used, which is presumed to have been defined as a certificate authority in the RACF database. The label CA4PartnerCompany should be added to the iked.conf file as a recognized certificate authority as follows:

         ```
         SupportedCertAuth CA4PartnerCompany
         ```

         **Guideline:** For more efficient processing of certificates when the IKED is using the native certificate service, you should code SupportedCertAuth for each acceptable certificate authority that will be used to sign certificates for remote IKE peers.

      3) Configure a KeyExchangeOffer statement that defines the parameters for the phase 1 negotiation, including type of peer authentication, strength of encryption, and how often the phase 1 keys are refreshed. Because KeyExchangeOffer statements are reusable, give it a descriptive name as follows:

         ```
         KeyExchangeOffer RSA-SHA1-3DES-DH2
         {   HowToEncrypt  3DES
         HowToAuthMsgs   SHA1
         HowToAuthPeers  RsaSignature
         ```
4) Decide whether NAT traversal will be allowed.

In this example, the following parameter is used:

```
AllowNat No
```

5) Determine the negotiation mode. Main mode is used for phase 1, providing added security by encrypting the identities of the two IKE peers during the phase 1 negotiation.

6) Configure a KeyExchangeAction statement that defines the control information for the phase 1 negotiation. The key exchange action determines the mode of the phase 1 negotiation and the parameters that are included in the KeyExchangeOffer statement. Although multiple KeyExchangeOffer statements are acceptable, only one is required. Both peers must agree on the parameters. Use the KeyExchangeOffer statement that was configured in step “7.a.iii” on page 960:

```
KeyExchangeAction Main-RSA-SHA1-3DES-DH2
{
    HowToInitiate main
    HowToRespondIKEv1 main
    KeyExchangeOfferRef RSA-SHA1-3DES-DH2
}
```

7) Configure a LocalSecurityEndpoint statement and RemoteSecurityEndpoint statement. In this example, the local security endpoint is the local host. An identity and IP address of the local IKE peer is required as follows:

```
LocalSecurityEndpoint  Public_IKED
{
    Identity       IpAddr  9.2.2.2
    Location       9.2.2.2
}
```

Similarly, the same information is needed for remote hosts. Notice that in the RemoteSecurityEndpoint statement, an IP address range is specified for both identity and location. Although it is possible to configure a RemoteSecurityEndpoint statement for every host in the remote subnetwork, unless they have unique key exchange requirements, it is not necessary. Wildcards can be used for the Identity and Location parameters. Any of the identity types can potentially contain wildcards to include a group of remote hosts with similar identities.

```
RemoteSecurityEndpoint   ZoneB_IKED
{
    Identity      IpAddr   9.4.0.0/16
    Location      9.4.0.0/16
    CaLabel       CA4PartnerCompany
}
```

The use of an IPv4 address on the Identity parameter for the Local_IKED security endpoint requires that the X.509 digital certificate for the local IKE daemon include the IPv4 address in the Subject Alternative Name field of the certificate. The use of an IPv4 subnet on the Identity parameter for the ZoneB_IKED security endpoint requires that an IPv4 address within that subnet (9.4.0.0/16) appear in the Subject Alternative Name field of the X.509 digital certificate for the remote IKE daemon.

The inclusion of the CaLabel parameter in the ZoneB_IKED security endpoint emphasizes the fact that the local host requests that the remote host use only certificates that are signed by the certificate authority that is identified by the label CA4PartnerCompany.
**Rule:** For RSA signature mode authentication, the identity of a security endpoint must be contained in its X.509 digital certificate, either in the Subject Name field or the Subject Alternative Name field.

For detailed specifications on the use of wildcards in the RemoteSecurityEndpoint statement, see *z/OS Communications Server: IP Configuration Reference*.

8) Configure a KeyExchangeRule statement that includes the two endpoints and the key exchange action:

```plaintext
KeyExchangeRule ZoneB_KeyExRule1
{
    LocalSecurityEndpointRef Public_IKED
    RemoteSecurityEndpointRef ZoneB_IKED
    KeyExchangeActionRef Main-RSA-SHA1-3DES-DH2
}
```

9) Include the key exchange rule in the KeyExchangePolicy statement:

```plaintext
KeyExchangePolicy
{
    KeyExchangeRuleRef ZoneB_KeyExRule1
}
```

b) Configure an IpDynVpnAction statement that defines the parameters of the phase 2 negotiation as follows:

1) Determine the required type and strength of IPSec protection for the phase 2 Security Association.

   In this example, there is a unique requirement for each traffic type. Therefore, there are two types of IPSec protection for each type of traffic as follows:

   - **EE traffic** - strong encryption: ESP, 3DES
     - strong ESP authentication: Hmac SHA1
   - **Normal FTP traffic** - strong AH authentication, Hmac SHA1

   This information eventually translates into two IpDataOffer statements.

2) Determine whether tunnel or transport mode is required.

   Tunnel mode is required only if either endpoint of the Security Association is a secure gateway. The choice is optional in a host-to-host configuration, but transport mode is typically used.

3) Configure IpDataOffer statements that define the parameters of the phase 2 negotiation.

   - **Authenticated offer for FTP:**

     ```plaintext
     IpDataOffer TRAN-AHSHA-NOENCR
     {
         HowToEncap Transport
         HowToEncrypt DoNot
         HowToAuth   AH HMAC_SHA1
         RefreshLifetimeProposed 240
         RefreshLifetimeAccepted 120 480
         RefreshLifeSizeProposed  none
         RefreshLifeSizeAccepted none
     }
     ```

   - **Encrypted and authenticated offer for EE:**

     ```plaintext
     IpDataOffer TRAN-ESPSHA-3DES
     {
         HowToEncap Transport
         HowToEncrypt 3DES
         HowToAuth    ESP HMAC_SHA1
         RefreshLifetimeProposed 240
         RefreshLifetimeAccepted 120 480
         RefreshLifeSizeProposed none
         RefreshLifeSizeAccepted none
     }
     ```

4) Determine which peer is allowed to initiate the negotiation.
Because the EE VPN activates when outbound EE traffic is detected, you need to be able to start the negotiation locally. The remote host initiates the negotiation of the Security Association for the FTP control connection, so local initiation is not required. The FTP data connection is initiated from the local host, so to activate the Security Association, local initiation is required.

5) Configure an IpDynVpnAction statement that defines the control information for the phase 2 negotiation.

The IpDynVpnAction statement can control which host is allowed to initiate the negotiation. You must allow the IPSec VPN for the FTP control connection to be initiated by the remote peer, and the data connection by the local host. EE should be allowed to initiate an IKE negotiation locally.

• Authenticated VPN action for FTP:

```plaintext
IpDynVpnAction FTP-vpnaction
{
  Initiation          either
  InitiateWithPfs    group2
  AcceptablePfs      group2
  VpnLife             1440
  IpDataOfferRef      TRAN-AHSHA-NOENC
}
```

• Encrypted and authenticated VPN action for EE traffic:

```plaintext
IpDynVpnAction EE-vpnaction
{
  Initiation           localonly
  InitiateWithPfs     group2
  AcceptablePfs       group2
  VpnLife             1440
  IpDataOfferRef       TRAN-ESP SHA-3DES
}
```

c) Decide how the Security Association is to be activated as follows:

1) Configure an optional LocalDynVpnPolicy statement, if command-line activated or autoactivated.

Neither the EE nor FTP VPNs require a LocalDynVpnPolicy statement, because neither is command-line activated or autoactivated.

2) Configure an optional IpLocalStartAction statement, if the Security Association is to be activated locally (that is, on-demand, command-line, or autoactivation) and one of the security endpoints is acting as a security gateway (that is, not a host-to-host Security Association). Include a reference to the IpLocalStartAction statement in the IP filter rule.

Before a phase 2 negotiation can initiate, the IKE daemon needs to know the IP addresses, ports, and protocols that the Security Association covers. In most cases, these can be inferred from the filter rule, or from the packet that started the on-demand activation. An IpLocalStartAction statement explicitly defines where these parameters are obtained. The granularity setting determines whether the information comes from the matching filter rule, or from the packet. By explicitly specifying packet, you can guarantee that a new Security Association is created for each connection request.

```plaintext
IpLocalStartAction ZoneB-Start-Action
{
  AllowOnDemand      yes
  LocalPortGranularity packet
  RemotePortGranularity packet
  ProtocolGranularity packet
  LocalIpGranularity   packet
  RemoteIpGranularity   packet
  LocalSecurityEndpointRef Public_IKED
  RemoteSecurityEndpointRef ZoneB_IKED
}
```
In this example, specifying packet is not required. IKE detects that the filter rule has a range of ports specified and resorts to packet granularity instead of the default of rule. Specifying packet is required, however, if the EE and FTP rules had all ports specified. In that case, one Security Association is negotiated for all ports, not a single port. To avoid confusion, it is better to specify your intention.

3) Set the global PreDecap parameter of the IpFilterPolicy statement to off, or create an IpFilterRule statement that allows IPSec traffic (AH and ESP).

When the system begins to process encapsulated traffic, the encapsulated packets are subject to filtering. The encrypted and authenticated packets are denied unless they are explicitly allowed. There are two options to configure this that are subtly different. The first is less restrictive, allowing AH and ESP packets from anywhere and not subjecting them to filtering until after the packets have had their IPSec headers removed. The second method is to add an IpFilterRule statement that explicitly permits the IPSec-encapsulated traffic. This option adds an additional layer of security, in that you can control exactly who is allowed to send encrypted traffic. This protects system resources by preventing the processing of IPSec packets unnecessarily, such as might happen in the case of a malicious attack of IPSec packets. Although more secure, this solution is less efficient because it requires additional processing resources to filter all IPSec-encapsulated traffic.

For the first option, in the main IpFilterPolicy block, code PreDecap off as follows:

```
IpFilterPolicy
{
    PreDecap off
}
```

For the second option, configure a filter rule in the IpFilterPolicy block that explicitly allows AH and ESP traffic as follows:

```
IpFilterRule
{
    IpSourceAddr          9.2.2.2
    IpDestAddrSet         9.4.0.0/16
    IpService              AH-traffic
    {
        Protocol                AH
        Direction               bidirectional
        Routing                 local
        SecurityClass           0
    }
    IpService              ESP-traffic
    {
        Protocol                ESP
        Direction               bidirectional
        Routing                 local
        SecurityClass           0
    }
    IpGenericFilterRef    permit-nolog
}
```

**Tip:** In most cases, unless the extra security is deemed a necessity, use the PreDecap off global option to allow IPSec packets to flow with minimum overhead.

7. Define an IpFilterRule statement for each set of data endpoints.

The secure host and subnetwork B represent the data endpoints. The IpService statements were defined in step “2” on page 958. Place the IpDynVpnAction statements that were created in step “6” on page 960 with the appropriate rule.

```
IpFilterRule
{
    IpSourceAddrRef         PublicServerAddress
    IpDestAddrSetRef        ZoneB-subnet
    IpServiceRef            IKE-local
    IpServiceGroupRef       SecureFTPServer
    IpGenericFilterActionRef permit-nolog
}
```
Because both IKE and Secure FTP need to be permitted without IPSec protection, an IpFilterRule statement for both is not needed. The two services can be combined into one rule.

**Tip:** Any services that share the same data endpoints and the same security requirements can be placed together in one IpFilterRule statement.

8. Include the IpFilterRule statements in the IpFilterPolicy block.

   The IpFilterRule statement allowing IKE traffic should always be at the top of the list. The rest of the IpFilterRule statements are disjointed, and their relative placement within the IpFilterPolicy is irrelevant.

   **Tip:** If it is known that one particular type of traffic is the most frequent, placing that rule near the top of the list results in faster filter lookups.

9. Define an IP filter group for each zone and include the IpFilterRule statements that belong to that zone.

   Although the creation of reference objects and groups is not mandatory, they provide for ease of maintenance as the IP security policy grows more complex.

   A completely configured policy, including all objects and their references, is as follows:

```bash
# IpFilterPolicy for secure public server
IpFilterPolicy {
  PreDecap off
  IpFilterGroupRef ZoneB
}

KeyExchangePolicy {
  KeyExchangeRuleRef ZoneB_KeyExRule1
}

##### All reusable statements follow #######

10. Include all configured statements in the stack-specific IP security configuration file.

**Steps for configuring the partner company with NAT model (host-to-host with IPSec)**

In the partner company with NAT model, the partner company model topology is modified to include private addressing in the private network of each partner company, with a NAT device in front of each private network.

**Before you begin**

The following statements and concepts are covered in the discussion of this model:

- AllowNat and NatKeepAliveInterval parameters on the KeyExchangePolicy and KeyExchangeAction statements
- IKE traffic on UDP port 4500, in addition to port 500
- NAT implications for host-to-host dynamic IKE negotiations:
  - Local and remote data endpoints
  - Local and remote security endpoints
  - IKE initiator and responder roles
  - Restriction on HowToAuth protocol (AH not supported)
- Using wildcards for location and identity
- RSA signature peer authentication
- Certificates and certificate authorities
- CaLabel
- SupportedCertAuth

“Steps for configuring the partner company model (host-to-host with IPSec)” on page 957 assumed a network topology with both partner companies using public IP addresses in their internal networks. Often one or both businesses have an internal network that uses IETF-defined private IP addresses (10.0.0.0/8, 172.16.0.0/12, and 192.168.0.0/16). Private IP addresses cannot be routed outside an internal network. Network address translation (NAT) is used to create a mapping of private addresses to public addresses and perform the necessary translation as packets traverse the NAT device.

When IPSec Security Associations traverse a NAT, there are problems because the NAT is unable to update IP addresses and checksums that are part of the encapsulated data (encrypted, authenticated, or both). The IETF has defined a solution known as NAT traversal (NATT) that allows IPSec Security Associations to successfully traverse a NAT device.
Figure 120 on page 970 shows the partner company with NAT topology when the partner company model topology has been modified to include private addressing in each partner company’s private network with a NAT device in front of each private network.

The steps in this topic will describe the configuration considerations and requirements when the NATT solution is implemented to traverse NAT devices in a host-to-host environment. The partner company with NAT model has the same basic security requirements as the partner company model. Configuration statements added or changed for the partner company with NAT model are shown in bold. The example describes the policy for partner company 1 (PCO1).

For this example, assume you must meet the following requirements to allow network communications from a partner company (PCO2) in an untrusted zone B behind a NAT over a connected network (9.4.0.0/16) to a server on this host that is behind a NAT:

- IKE traffic from untrusted zone B that is behind a NAT is allowed to this host that is behind a NAT.
- Secure FTP traffic (using TLS/SSL) from untrusted zone B is allowed to a secure FTP server running on this host.
- Enterprise Extender (EE) traffic from untrusted zone B is allowed to an EE service running on this host using a dynamic IPSec tunnel with strong encryption and authentication.
- FTP traffic from untrusted zone B is allowed to an FTP server running on this host using a dynamic IPSec tunnel with strong authentication.
- The dynamic IPSec tunnel for EE is activated when outbound EE traffic is detected (on-demand activation).
- A dynamic IPSec tunnel for normal FTP control activates for each remote host that initiates an FTP connection (remote activation).
- A dynamic IPSec tunnel for normal FTP data activates for each remote host that initiates an FTP data connection (remote activation).
- Peers authenticate themselves using the RSA signature method.

**Procedure**

Perform the following steps to meet these requirements and configure the partner company with NAT model.

1. For each zone, determine what services are allowed:
2. Define an IpService statement for each wanted service.

• IKE traffic

When NAT traversal is allowed, IKE uses UDP port 500 and port 4500 for message exchanges. NAT traversal is controlled by the AllowNat parameter on the KeyExchangePolicy and KeyExchangeAction statements.

```
IpService IKE-local-500
{
  SourcePortRange 500
  DestinationPortRange 500
  Protocol          UDP
  Direction         bidirectional
  Routing           local
  SecurityClass     0
}
IpService IKE-local-4500
{
  SourcePortRange 4500
  DestinationPortRange 4500
  Protocol          UDP
  Direction         bidirectional
  Routing           local
  SecurityClass     0
}
```

• Normal FTP traffic

When a NAT is being traversed, FTP clients typically need to use passive mode (PASV) or extended passive mode (EPSV) to connect to the FTP server, allowing inbound connections but not outbound connection requests. For more information on active and passive mode FTP, see “Considerations for IPsec-encapsulated FTP traffic when traversing a NAT” on page 1009.

Two services are required, one for the control connection and one for the data connection. The range of server ports specified for the data connection reflects the port range specified for PASSIVEDATAPORTS in the server’s FTP.DATA file. For more information on PASSIVEDATAPORTS, see z/OS Communications Server: IP Configuration Reference.

The following definitions show the services required for the FTP server for EPSV mode:

```
IpService FTPServer-Control
{
  SourcePortRange 21
  DestinationPortRange 1024 65535
  Protocol          tcp
  Direction         bidirectional InboundConnect
  Routing           local
  SecurityClass     0
}
IpService FTPServer-Data-Passive
{
  SourcePortRange 50000 50200
  DestinationPortRange 1024 65535
  Protocol          tcp
  Direction         bidirectional InboundConnect
  Routing           local
  SecurityClass     0
}
```

• Secure FTP traffic

Again, when a NAT is being traversed, FTP clients typically need to use passive mode (PASV) or extended passive mode (EPSV) to connect to the FTP server, allowing inbound connections but not
outbound connection requests. Two services are required, one for the control connection and one for the data connection.

3. Determine the data endpoints that are to be protected.

In this case, the local data endpoint is the private address of the server, local IP address 10.1.1.1.

The remote data endpoint is the partner company’s internal network. The z/OS implementation does not require you to code private addresses for the remote endpoint; the network address translated public addresses should be configured as the remote data endpoint. In this example, the private addresses in the PCO2 internal network (10.2.0.0/16) are translated into the public address range 9.4.0.0/16. Thus, the remote subnetwork is 9.4.0.0/16.

4. Determine what level of security is needed between each set of data endpoints.

IKE traffic - permit
Secure FTP traffic - permit
EE traffic - IPSec encryption and authentication
FTP traffic - IPSec authentication

5. Configure an IpGenericFilterAction statement for the level of security that is required.

The requirements stated that IKE and secure FTP should be allowed, and that EE and normal FTP traffic required IPSec protection. Because no logging requirements were specified, two actions are needed, permit and ipsec.

<table>
<thead>
<tr>
<th>IpGenericFilterAction</th>
<th>permit-nolog</th>

<tr>
<td>IpFilterLogging</td>
<td>no</td>
</tr>
</tbody>
</table>

6. If IPSec is required between any two endpoints, take the following actions:

   a) Configure a key exchange policy that defines the parameters of the phase 1 negotiation as follows:
1) Determine the required type and strength of protection for the phase 1 Security Association. Phase 1 Security Associations must use both authentication and encryption. Because strong encryption was specified for phase 2, use strong encryption for phase 1:

- Authentication, SHA1 algorithm
- Encryption, 3DES algorithm
- DHGroup, Diffie-Hellman Group2

**Tip:** The greater the Diffie-Hellman group specified, the greater the protection provided.

2) Decide what type of peer authentication is used:

**RSA signature**

Because the remote data endpoint represents multiple hosts in this example, RSA signature is used. RSA signature authentication provides greater flexibility, scalability, and security than pre-shared key authentication. Because there are potentially multiple remote peers in the partner company's subnet, RSA signature is a reasonable choice.

The use of RSA signature requires setup of RACF certificates and certificate authority information. Both IKE peers need access to a key ring with at least one X.509 digital certificate to identify itself. To set up the IKE daemon for certificates, see Appendix E, "Steps for preparing to run IP security," on page 1331. The site should decide what certificate authorities are recognized. A certificate authority can be an outside commercial entity, or it can be defined locally in RACF. For information about installing certificate authorities in RACF, see z/OS Security Server RACF Security Administrator's Guide.

In this example, the IKEv1 protocol is used and the IKE daemon is using the native certificate service. A certificate authority with label CA4PartnerCompany is used, which is presumed to have been defined as a certificate authority in the RACF database. The label CA4PartnerCompany should be added to the iked.conf file as a recognized certificate authority as follows:

```
SupportedCertAuth CA4PartnerCompany
```

**Guideline:** For more efficient processing of certificates when the IKED is using the native certificate service, you should code SupportedCertAuth for each acceptable certificate authority that will be used to sign certificates for remote IKE peers.

3) Configure a KeyExchangeOffer statement that defines the parameters for the phase 1 negotiation, including type of peer authentication, strength of encryption, and how often the phase 1 keys are refreshed. Because KeyExchangeOffer statements are reusable, give it a descriptive name as follows:

```
KeyExchangeOffer RSA-SHA1-3DES-DH2
{
    HowToEncrypt  3DES
    HowToAuthMsgs  SHA1
    HowToAuthPeers RSAsignature
    DHGroup         Group2
    RefreshLifetimeProposed  480
    RefreshLifetimeAccepted  240 1440
    RefreshLifesizeProposed  none
    RefreshLifesizeAccepted  none
}
```

4) Decide whether NAT traversal will be allowed.

The AllowNat parameter on the KeyExchangePolicy and KeyExchangeAction statements allows IKE to advertise NAT traversal support. When a phase 1 Security Association is being negotiated, if both IKE peers support NAT traversal, several IKE payloads are exchanged that allow the peers to determine if one or more NAT devices are being traversed. If a NAT is being traversed, the IKE peers negotiate a UDP-encapsulated transport mode or UDP-encapsulated tunnel mode phase 2 Security Association to allow IPSec traffic to traverse the NATs.
successfully. If a NAT is not being traversed, a standard transport or tunnel mode phase 2 Security Association is negotiated.

The AllowNat parameter can be specified on the overall KeyExchangePolicy statement or for a specific KeyExchangeAction statement. If AllowNat is No, IKE does not advertise its support for NAT traversal. You might want to disable NAT traversal for interoperability purposes (certain remote resources might not be able to tolerate NAT traversal protocols) or security concerns (for example, NAT traversal exposes private internal addresses to the IKE peer). If NAT traversal is disabled and there is a NAT device in the path, ipsec processing might fail to negotiate the Security Association or fail to send data over the Security Association.

For this model, allow NAT traversal support to be advertised for all phase 1 Security Associations by coding the following parameter on the KeyExchangePolicy statement:

| AllowNat Yes |

A NatKeepAliveInterval parameter is also provided on the KeyExchangePolicy statement. A NAT keep-alive timer is maintained to ensure that NAT mappings do not expire. If z/OS is behind a NAT, a NAT keep-alive timer is started with the interval specified on the NatKeepAliveInterval parameter. If z/OS is behind a NAT that is using static mappings that will not expire, the NatKeepAliveInterval parameter should be set to 0. It is not necessary to run a NAT keep-alive timer in this case.

For this model, because static mapping is being used for the NAT in front of PCO1, the NatKeepAliveInterval parameter is set to 0:

| NatKeepAliveInterval 0 |

5) Determine the negotiation mode. Main mode is used for phase 1 in this example, providing added security by encrypting the identities of the two IKE peers during the phase 1 negotiation.

6) Configure a KeyExchangeAction statement that defines the control information for the phase 1 negotiation. The key exchange action determines the mode of the phase 1 negotiation and the parameters that are included in the KeyExchangeOffer statement. Although multiple KeyExchangeOffer statements are acceptable, only one is required. Both peers must agree on the parameters. Use the KeyExchangeOffer statement that was configured previously:

```
KeyExchangeAction Main-RSA-SHA1-3DES-DH2
{  HowToInitiate main
    HowToRespondIKEv1 main
    KeyExchangeOfferRef RSA-SHA1-3DES-DH2
}
```

7) Configure a LocalSecurityEndpoint statement and RemoteSecurityEndpoint statement. In this example, the local security endpoint is the local host. An identity and IP address of the local IKE peer is required as follows:

```
LocalSecurityEndpoint Local_IKED
{
    Identity Fqdn Server.PCO1.example.com
    Location 10.1.1.1
}
```

The value specified for Identity on the LocalSecurityEndpoint statement is sent to the remote peer to identify this endpoint. The remote peer uses this value to determine if a Security Association can be negotiated and which policy should be used. Identity can be specified in different formats, such as an IP address or fully qualified domain name.

The partner company model specified an IP address for Identity, and an IP address could be used in this model. However, PCO1's private IP address 10.1.1.1 is not meaningful in the PCO2 configuration, so one of the other Identity types was chosen. The fully qualified domain name (Fqdn) identifies the local security endpoint.
An identity and IP address are also needed for the remote hosts. Notice that in the following RemoteSecurityEndpoint statement, the Identity and Location attributes use a wildcard to include a group of remote hosts with similar identities. It is possible to use a wildcard for the values because the key exchange requirements are the same for the hosts included in the specified range.

The Identity attribute is specified as Fqdn (fully qualified domain name), and the Location attribute is the range of public IP addresses used by the PCO2 internal network. PCO2 internal private addresses are not coded because they have no meaning for PCO1.

```
RemoteSecurityEndpoint ZoneB_IKED
{
    Identity  Fqdn  *.PCO2.example.com
    Location  9.4.0.0/16
    CaLabel   CA4PartnerCompany
}
```

The use of a fully qualified domain name on the Identity parameter for the Local_IKED security endpoint requires that the X.509 digital certificate for the local IKE daemon include the fully-qualified domain name in the Subject Alternative Name field of the certificate. The use of a wild-carded domain name on the Identity parameter for the ZoneB_IKED security endpoint requires that a fully-qualified domain name ending with .PCO2.example.com appear in the Subject Alternative Name field of the X.509 digital certificate for the remote IKE daemon.

The inclusion of the CaLabel parameter in the ZoneB_IKED security endpoint emphasizes the fact that the local host requests that the remote host use only certificates that are signed by the certificate authority that is identified by the label CA4PartnerCompany.

**Rule:** For RSA signature mode authentication, the identity of a security endpoint must be contained in its X.509 digital certificate, either in the Subject Name field or the Subject Alternative Name field.

For detailed specifications on the use of wildcards in the RemoteSecurityEndpoint statement, see z/OS Communications Server: IP Configuration Reference.

8) Configure a KeyExchangeRule statement that includes the two endpoints and the key exchange action:

```
KeyExchangeRule ZoneB_KeyExRule1
{
    LocalSecurityEndpointRef Local_IKED
    RemoteSecurityEndpointRef ZoneB_IKED
    KeyExchangeActionRef Main-RSA-SHA1-3DES-DH2
}
```

9) Include the key exchange rule in the KeyExchangePolicy statement block. Also include the AllowNat parameter:

```
KeyExchangePolicy
{
    AllowNat Yes
    KeyExchangeRuleRef ZoneB_KeyExRule1
}
```

b) Configure an IpDynVpnAction statement that defines the parameters of the phase 2 negotiation as follows:

1) Determine the required type and strength of IPSec protection for the phase 2 Security Association.

In this example, there is a unique requirement for each traffic type. Therefore, there are two types of IPSec protection for each type of traffic as follows:

```
EE traffic - strong encryption: ESP, 3DES
    strong ESP authentication: Hmac SHA1
Normal FTP traffic - strong ESP authentication, Hmac SHA1
```
The partner company model used AH authentication for normal FTP traffic, but the NATT solution defined by the IETF is based on the ESP protocol. The AH protocol is not supported for NATT, and ESP authentication is used in this model.

This information eventually translates into two IpDataOffer statements.

2) Determine whether tunnel or transport mode is required.

Tunnel mode is required only if either endpoint of the Security Association is a secure gateway. The choice is optional in a host-to-host configuration, but transport mode is typically used.

3) Configure IpDataOffer statements that define the parameters of the phase 2 negotiation.

- Authenticated offer for FTP:

```plaintext
IpDataOffer TRAN-ESP-HMAC_SHA1
{
  HowToEncap Transport
  HowToEncrypt DoNot
  HowToAuth    ESP HMAC_SHA1
  RefreshLifetimeProposed 240
  RefreshLifetimeAccepted 120 480
  RefreshLifeSizeProposed none
  RefreshLifeSizeAccepted none
}
```

- Encrypted and authenticated offer for EE:

```plaintext
IpDataOffer TRAN-ESP-HMAC_SHA1
{
  HowToEncap Transport
  HowToEncrypt 3DES
  HowToAuth    ESP HMAC_SHA1
  RefreshLifetimeProposed 240
  RefreshLifetimeAccepted 120 480
  RefreshLifeSizeProposed none
  RefreshLifeSizeAccepted none
}
```

4) Determine which peer is allowed to initiate the negotiation.

When an IKE peer is behind a NAT device, there are implications regarding which peer can initiate. In a host-to-host configuration, IKE should initiate only to a peer whose IP address is unambiguous. If the peer is not behind a NAT, or if the peer’s NAT mapping is static, the address is unambiguous. In this model, assume that static mapping is being used for both PCO1 and PCO2.

Because the EE VPN activates when outbound EE traffic is detected, you need to be able to start the negotiation locally. For PASV mode or EPSV mode FTP, both the FTP control connection and the FTP data connection initiate the negotiation of the Security Association remotely, so local initiation is not required.

5) Configure an IpDynVpnAction statement that defines the control information for the phase 2 negotiation.

The IpDynVpnAction statement can control which host is allowed to initiate the negotiation. Both the FTP control connection and data connection will be initiated remotely. EE should be allowed to initiate an IKE negotiation locally.

- Authenticated VPN action for FTP:

```plaintext
IpDynVpnAction FTP-vpna
{
  Initiation           remoteonly
  InitiateWithPfs     group2
  AcceptablePfs       group2
  VpnLife              1440
  IpDataOfferRef       TRAN-ESP-HMAC_SHA1
}
```
- Encrypted and authenticated VPN action for EE traffic:

```
IpDynVpnAction EE-vpnaction
{
  Initiation           localonly
  InitiateWithPfs      group2
  AcceptablePfs        group2
  VpnLife              1440
  IpDataOfferRef       TRAN-ESP SHA-3DES
}
```

c) Decide how the Security Association is to be activated as follows:

1) Configure an optional LocalDynVpnPolicy statement, if command-line activated or autoactivated.

Neither the EE nor FTP VPNs require a LocalDynVpnPolicy statement, because neither is command-line activated or autoactivated.

2) Configure an optional IpLocalStartAction statement, if the Security Association is to be activated locally (that is, on-demand, command-line, or autoactivated) and one of the security endpoints is acting as a security gateway (that is, not a host-to-host Security Association). Include a reference to the IpLocalStartAction statement in the IP filter rule.

Before a phase 2 negotiation can initiate, the IKE daemon needs to know the IP addresses, ports, and protocols that the Security Association covers. In most cases, these can be inferred from the filter rule, or from the packet that started the on-demand activation. An IpLocalStartAction statement explicitly defines where these parameters are obtained. The granularity setting determines whether the information comes from the matching filter rule, or from the packet. By explicitly specifying packet, you can guarantee that a new Security Association is created for each connection request.

```
IpLocalStartAction           ZoneB-Start-Action
{
  AllowOnDemand             yes
  LocalPortGranularity      packet
  RemotePortGranularity     packet
  ProtocolGranularity       packet
  LocalIpGranularity        packet
  RemoteIpGranulatiry       packet
  LocalSecurityEndpointRef  Local_IKED
  RemoteSecurityEndpointRef ZoneB_IKED
}
```

In this example, specifying packet for LocalPortGranularity and RemotePortGranularity is not required. IKE detects that the filter rule has a range of ports specified and resorts to packet granularity instead of the default of rule. Specifying packet is required, however, if the EE rules had all ports specified. In that case, one Security Association is negotiated for all ports, not a single port. To avoid confusion, it is better to specify your intention.

3) Set the global PreDecap parameter of the IpFilterPolicy statement to off, or create an IpFilterRule statement that allows IPSec traffic (AH and ESP).

In this example, set PreDecap off in the IpFilterPolicy statement.

7. Define an IpFilterRule statement for each set of data endpoints.

The secure host and zone B represent the data endpoints. The IpService statements were defined previously. Place the IpDynVpnAction statements that were created previously with the appropriate rule. Notice that the parameters of the IpGenericFilterAction statement include ipsec as well as permit and deny. Because no logging requirements were specified, two actions are needed, permit and ipsec.

```
IpFilterRule              ZoneB-Permitted-traffic
{
  IpSourceAddrRef           PrivateServerAddress
  IpDestAddrSetRef          ZoneB-subnet
  IpServiceRef              IKE-local-500
  IpServiceRef              IKE-local-4500
  IpServiceGroupRef         SecureFTPServer
  IpGenericFilterActionRef  permit-nolog
}
```
Because IKE port 500, IKE port 4500, and secure FTP without IPSec protection are permitted, a separate IpFilterRule statement for each is not needed. The services can be combined into one IpFilterRule statement.

**Tip:** Any services that share the same data endpoints and the same security requirements can be placed together in one IpFilterRule statement.

8. Include the IpFilterRule statements in the IpFilterPolicy block.

9. Define an IP filter group for each zone and include the IpFilterRule statements that belong to that zone. Although the creation of reference objects and groups is not mandatory, they provide for ease of maintenance as the IP security policy grows more complex.

10. Include all configured statements in the stack-specific IP security configuration file.

**Results**

A completely configured policy, including all objects and their references, is as follows:

```plaintext
# IpFilterPolicy for secure public server
IpFilterPolicy
{
    PreDecap        off
    IpFilterGroupRef ZoneB
}

KeyExchangePolicy
{
    AllowNat     Yes
    NatKeepAliveInterval 0
    KeyExchangeRuleRef ZoneB_KeyExRule1
}

# IpFilterRules
#
# defines:
# data endpoints
# Allowed services
# Actions (permit, deny, ipsec)

IpFilterRule ZoneB-Permitted-traffic
{
    IpSourceAddrRef    PrivateServerAddress
    IpDestAddrSetRef   ZoneB-subnet
    IpServiceRef       IKE-local-500
    IpSupportedAction   permit
    IpLocalStartActionRef ZoneB-Start-Action
}
```

Steps for configuring the partner company with NAPT model (host-to-host with IPSec)
The partner company with NAPT model modifies the partner company with NAT model, replacing the NAT device in front of the internal network of each partner company with a NAPT device.

Before you begin
The following statements and concepts are covered in the discussion of this model:

- Using wildcard values for the remote port for IKE traffic
- NAPT implications for host-to-host dynamic IKE negotiations:
  - Local and remote data endpoints
  - Local and remote security endpoints
  - IKE initiator and responder roles

The partner company model assumed a network topology with both partner companies using public IP addresses in their internal networks. The partner company with NAT model modified the partner company model to include private addressing in the private network of each partner company, with a NAT device in front of each private network. Both NAT devices used static one-to-one address mappings.

The partner company with NAPT model modifies the partner company with NAT model, replacing the NAT device in front of the partner company’s internal network with a NAPT device. The NAPT device uses many-to-one address and port mappings. The NAT in front of the z/OS host continues to use static one-to-one address mappings.

Figure 121 on page 983 shows the partner company with NAPT topology.
Figure 121. Partner company with NAPT model

The partner company with NAPT model has the same basic security requirements as the partner company with NAT model. One difference is that IPSec protection for Enterprise Extender (EE) traffic has been eliminated from the example. EE traffic is not compatible with the use of NAPT, with or without IPSec protection. For more information, see “Enterprise Extender considerations when traversing a NAT” on page 1009.

This example includes only the configuration steps that are impacted by a change from static one-to-one address mappings to NAPT mappings. Configuration statements added or changed for the partner company with NAPT model are shown in bold. The example describes the policy for partner company 1 (PCO1).

For this example, assume you must meet the following requirements to enable network communications from a partner company (PCO2) in an untrusted zone B behind a NAPT (9.4.4.4), over a connected network, to a server on this host that is behind a NAT, using static one-to-one address mapping:

- IKE traffic from untrusted zone B is allowed to this host.
- Secure FTP traffic (using TLS/SSL) from untrusted zone B is allowed to a secure FTP server running on this host.
- FTP traffic from untrusted zone B is allowed to an FTP server running on this host using a dynamic IPSec tunnel with strong authentication.
- A dynamic IPSec tunnel for normal FTP control activates for each remote host that initiates an FTP connection (remote activation).
- A dynamic IPSec tunnel for normal FTP data activates for each remote host that initiates an FTP data connection (remote activation).
- Peers authenticate themselves using the RSA signature method.

Procedure

Starting with the partner company with NAT policy, the following changes need to be made to meet these requirements when there is a NAPT in front of the partner company's internal network (Zone B):

- Modify the IpService statements for the IKE traffic to specify a wildcard value for the remote port.

The NAPT will update both the IP address and port values of an IKE packet, so that the traffic can no longer be described with a constant value of 500 or 4500.
• Modify the remote data endpoint to reflect the NAPT’s single IP address, 9.4.4.4.

The remote data endpoint is the partner company's internal network. The z/OS implementation does not require you to code private addresses for the remote endpoint; the network address translated public address should be configured as the remote data endpoint. In this example, the private addresses in the PCO2 internal network (10.2.0.0/16) are translated into the public address 9.4.4.4. Thus, the remote data endpoint is 9.4.4.4.

Results

A completely configured policy, including all objects and their references, is as follows:

```plaintext
# IpFilterPolicy for secure public server
IpFilterPolicy
{   PreDecap off
    IpFilterGroupRef ZoneB
}

Steps for configuring the branch office model: Part 1 (host-to-gateway with IPSec)

The branch office model part 1 consists of two networks whose IP connectivity relies on the Internet. The server is protecting traffic that originates from hosts outside the internal network, which at some point is routed over the Internet.

Before you begin

The following topics are covered in the discussion of this model:

- Host-to-gateway
- Gateway-to-gateway
- Autoactivation
- Command-line activation
- Using wildcards for location and identity
- Pre-shared key peer authentication

Figure 122 on page 988 shows the branch office portion of the security model network.
Transport-mode IPSec is used exclusively for transporting encrypted data directly between two hosts. Tunnel-mode IPSec encapsulation must be used if one of the security endpoints is a security gateway routing traffic for any number of hosts. In the branch office model, there can be multiple hosts behind a security gateway that is providing the security mechanism for all hosts that are behind the security gateway. The base assumption is that the local secure server represents a single data endpoint and a single security endpoint, whereas the remote subnetwork represents multiple data endpoints which share a common security endpoint, namely the security gateway host. Traffic from the local server to the branch office gateway is IPSec protected, while traffic from the branch office gateway to the hosts behind the security gateway need not be encrypted or even filtered.

As in the previous models, a complete IP security policy defines the traffic that is allowed between the local server and the zone representing the branch office. However, the difference lies primarily in where the remote security endpoint is situated. In the previous examples, all of the IPSec protection was provided on a host-to-host basis. Each set of communicating endpoints had a single dynamic VPN that represented a secure channel of communication between two hosts, local and remote. In contrast, any scenario that involves an IPSec security gateway can require that oneVPN carry traffic for multiple hosts. This difference is highlighted in this branch office example.

For this example, assume the following requirements to allow network communications from zone C, a branch office network (9.6.0.0/16), to a public IP address (9.3.3.3) on this host. The hosts on the branch office network connect to the Internet through the public branch office gateway server (9.5.5.5).

- Allow IKE traffic from branch office zone C to this host.
- Allow EE traffic from branch office zone C to an EE service running on this host, using a dynamic VPN with strong authentication and encryption. The VPN should be up when the stack initializes.
- Allow normal FTP traffic from branch office zone C to an FTP server running on this host, using a dynamic VPN with strong authentication and encryption. The VPN is command-line activated. Only one VPN should be established to carry all FTP traffic. There will not be one VPN per connection, but rather one Security Association will be negotiated for all of the remote FTP clients.

**Restriction:** Negotiating a single Security Association for multiple remote clients is possible only when the remote security endpoint is acting as a secure gateway.

- Peers authenticate themselves using the pre-shared key method.

**Procedure**

Perform the following steps to meet these requirements and configure part 1 of the branch office model.

1. Determine the number of zones to be protected.
   The branch office represents one zone, zone C.

2. For each zone, determine what services are allowed and define an IpService block for each wanted service.
   Services are defined by their protocols and the well-known ports they use.
The definitions that describe FTP traffic can be combined in an IP service group as follows:

```
IpServiceGroup               FTPServer
{                           
  IpService                  FTPServer-Control
  {                         
    SourcePortRange          21
    Protocol                 tcp
    Direction                bidirectional InboundConnect
    Routing                  local
    SecurityClass            0
  },
  IpService                  FTPServer-Data
  {                         
    SourcePortRange          20
    Protocol                 tcp
    Direction                bidirectional OutboundConnect
    Routing                  local
    SecurityClass            0
  },
  IpService                  FTPServer-Data-Passive
  {                         
    SourcePortRange          50000 50200
    Protocol                 tcp
    Direction                bidirectional InboundConnect
    Routing                  local
    SecurityClass            0
  }
}
```

The traffic pattern for Enterprise Extender can be defined in one IpService block as follows:

```
IpService                    Enterprise-Extender
{                           
  SourcePortRange            12000 12004
  DestinationPortRange       12000 12004
  Protocol                   udp
  Direction                  bidirectional
  Routing                    local
  SecurityClass              0
}
```

3. Determine the data endpoints to be protected.
   Typically, this is both a local and remote IP address or subnetwork.

   In this example, for the local host public IP address, 9.3.3.3, define the following statement:

```
IpAddr                       PublicServerAddressA1
{                           
  Addr                       9.3.3.3
}
```

For the remote subnet, 9.6.0.0/16, the following statement is defined:

```
IpAddrSet                    SubnetC
{                           
  Prefix                     9.6.0.0/16
}
```

Because it is necessary to permit IKE traffic between the local public server and the remote branch office gateway, the IP address of the remote gateway must also be defined as follows:

```
IpAddr                       BranchOfficeGateway
{                           
  Addr                       9.5.5.5
}
```

4. Determine what level of security is needed between each set of data endpoints.
   In this example, strong authentication and encryption is needed for both EE and FTP traffic, so ESP authentication and ESP encryption are used.
5. Configure an IpGenericFilterAction statement for the level of security that is required (permit, deny, ipsec), including whether the connection should be logged, as follows:

```
IpGenericFilterAction        ipsec
{ IpFilterAction             ipsec
}
```

6. If IPSec is required between any two endpoints, take the following actions:

   a) Configure a key exchange policy that defines the parameters of the phase 1 negotiation as follows:

      1) Determine the required type and strength of protection for the phase 1 Security Association.

         In this example, SHA1 authentication is used because it is more secure than MD5, and AES encryption is used because it is stronger than DES. Diffie-Hellman Group5 and Group14 are considered strong enough to generate keying material for AES using a 128 bit key. Group14 is used in this example.

      2) Decide what type of peer authentication to use.

         In this example, pre-shared key authentication is specified in the requirements. Typically, the RSA signature method is preferable, given its numerous advantages, but for the purposes of example the pre-shared key method is used here. Because there is only one remote IKE peer in the branch office scenario (the remote security gateway), and because it is relatively simple to configure, pre-shared key authentication is a reasonable choice.

      3) Configure a KeyExchangeOffer statement that defines the parameters for the phase 1 negotiation as follows:

         KeyExchangeOffer             SHA1-AES-PSK
         { HowToEncrypt               AES_CBC KeyLength 128
           HowToAuthMsgs              SHA1
           HowToAuthPeers             PresharedKey
           DHGroup                    Group14
         }

      4) Decide whether NAT traversal will be allowed.

         In this example, the following parameter is used:

         AllowNat No

      5) Determine the negotiation mode, Main or Aggressive.

         Because security is a priority in the branch office model, the more secure Main mode is used for the phase 1 negotiation.

      6) Configure a KeyExchangeAction statement as follows:

         KeyExchangeAction            Gold-PSK
         { HowToInitiate              main
           HowToRespondIKEv1          main
           KeyExchangeOfferRef        SHA1-AES-PSK
         }

      7) Configure a LocalSecurityEndpoint statement and RemoteSecurityEndpoint statement as follows:

         LocalSecurityEndpoint        Public_IKED
         { Identity                   IpAddr 9.3.3.3
           LocationRef               PublicServerAddressA1
         }

         RemoteSecurityEndpoint       ZoneC_IKED
         { Identity                   Fqdn gateway.BO.example.com
           LocationRef               BranchOfficeGateway
         }

990 z/OS Communications Server: IP Configuration Guide
8) Configure a KeyExchangeRule statement that includes the two endpoints, the key exchange action, and the pre-shared key as follows:

```plaintext
KeyExchangeRule ZoneC_KeyExRule1 {
  LocalSecurityEndpointRef Public_IKED
  RemoteSecurityEndpointRef ZoneC_IKED
  KeyExchangeActionRef Gold-PSK
  PresharedKey abracadabra
}
```

9) Include the KeyExchangeRule statement in the KeyExchangePolicy statement block, as follows:

```plaintext
KeyExchangePolicy {
  KeyExchangeRuleRef ZoneC_KeyExRule1
}
```

b) Configure an IpDynVpnAction statement defining the control of the phase 2 negotiation, as follows:

1) Determine the required type and strength of IPSec protection for the phase 2 Security Association.
   In this example, authentication is ESP HMAC_SHA1 and encryption is AES.

2) Determine whether tunnel or transport mode is required.
   Tunnel mode is required when one of the security endpoints is a security gateway.

3) Configure an IpDataOffer statement that defines the parameters of the phase 2 negotiation, as follows:

```plaintext
IpDataOffer SHA-AES-Tunnel {
  HowToEncap tunnel
  HowToEncrypt AES_CBC KeyLength 128
  HowToAuth ESP HMAC_SHA1
}
```

4) Determine which peer is allowed to initiate the negotiation.
   Because the EE VPN is up when the stack starts, you need to be able to start the negotiation locally (that is, autoactivate it). The FTP VPN is command-line activated, so you need to be able to start the negotiation locally.

5) Configure an IpDynVpnAction statement that defines the control information for the phase 2 negotiation, as follows:

```plaintext
IpDynVpnAction Gold-TunnelMode {
  Initiation either
  InitiateWithPfs group2
  AcceptablePfs group2
  IpDataOfferRef SHA-AES-Tunnel
}
```

c) Decide how the Security Association is activated.

1) Optionally, configure a local dynamic VPN policy, if command-line activated or autoactivated.

A LocalDynVpnRule statement is required for each Security Association because none are on-demand activated, five for the EE traffic and two for the FTP traffic, as follows:

```plaintext
LocalDynVpnRule ZoneC_VPN-EE1 {
  LocalIpRef PublicServerAddressA1
  RemoteIpSetRef SubnetC
  LocalDataPort 12000
  RemoteDataPort 12000
  Protocol UDP
  AutoActivate Yes
}
2) Configure an optional IpLocalStartAction statement, if the Security Association is to be activated locally (that is, on-demand, command-line, or autoactivation) and one of the security endpoints is acting as a security gateway (that is, not a host-to-host Security Association). Include a reference to the IpLocalStartAction statement in the IP filter rule.

If the local secure server initiates an IKE negotiation, it must be able to identify a remote IKE peer. However, in this case, the remote data endpoint is not a single host, but multiple endpoints in a subnetwork, ZoneC. The IpLocalStartAction statement is used to identify the remote IKE peer, and is required if the local IKE daemon initiates an ipsec connection with a remote security gateway.
3) Create an IpFilterRule statement that allows IPSec traffic (AH and ESP), or set the global IpFilterPolicy statement parameter PreDecap to off.

In this example, PreDecap off is used in the IpFilterPolicy statement.

7. Define an IpFilterRule statement for each set of data endpoints.

The rule should include the services that are allowed (one IpService statement for each allowed service), and the level of security that is required (a reference to the IpGenericFilterAction statement). If IPSec is required, create an IpFilterRule statement that allows IKE traffic (UDP, port 500). If NAT traversal is allowed, create an IpFilterRule statement that allows IKE UDP traffic on port 4500. See the IpAddr and IpAddrSet statements configured in step “3” on page 989.

```
IpFilterRule                 Rule1C
{                          
  IpSourceAddrRef          PublicServerAddressA1
  IpDestAddrRef            BranchOfficeGateway
  IpServiceRef             IKE
  IpGenericFilterActionRef permit
}
```

```
IpFilterRule                 Rule2C
{                          
  IpSourceAddrRef          PublicServerAddressA1
  IpDestAddrSetRef         SubnetC
  IpServiceRef             Enterprise-Extender
  IpServiceGroupRef        FTPServer
  IpGenericFilterActionRef ipsec
  IpDynVpnActionRef        Gold-TunnelMode
  IpLocalStartActionRef    StartZoneC
}
```

8. Define an IpFilterGroup statement for each zone and include the IpFilterRule statements that belong to that zone.

10. Include all configured statements in the stack-specific IP security configuration file.

**Results**

The following policy is a complete IP security policy for traffic from the local secure server to zone C, assuming that the reusable statements are included in the common IP security configuration file:

```
#-------------------------------------------------------
# Filter Policy for Secure Server
#-------------------------------------------------------

  }
}
Steps for configuring the branch office with NAT model (host-to-gateway with IPSec)
The branch office with NAT model modifies the branch office model topology to include a NAT in front of
the security gateway.

Before you begin
The following NAT implications for host-to-gateway dynamic IKE negotiations are covered in the
discussion of this model:

• Local and remote data endpoints
• Local and remote security endpoints
• IKE initiator and responder roles
• Restriction on HowToAuth protocol (AH not supported)

“Steps for configuring the branch office model: Part 1 (host-to-gateway with IPSec)” on page 987
assumed a network topology with both the host and the security gateway, as well as the hosts behind the
security gateway, using public IP addresses. Often one or both security endpoints are behind a NAT using a private IP address.

Modifying the branch office model topology to include a NAT in front of the security gateway, the branch office with NAT topology becomes as shown in Figure 123 on page 996:

![Diagram of branch office with NAT model](image)

**Figure 123. Branch office with NAT model**

This example will describe the configuration considerations and requirements when the NATT solution is implemented to traverse NAT devices in a host-to-security gateway environment. The branch office with NAT model has the same basic security requirements as the branch office model. Configuration statements added or changed for the branch office with NAT model are shown in bold. The example describes the policy for host 9.3.3.3.

For this example, assume the following requirements to enable network communications from zone C, a branch office network using private IP addresses (10.3.0.0/16), to a public IP address (9.3.3.3) on this host. The hosts on the branch office network connect to the Internet through the branch office gateway server, which is behind a NAT. In this model, the NAT has a static mapping of the security gateway’s private address 10.3.3.3 to the public address 9.5.5.5.

- Allow IKE traffic from the branch office zone C security gateway to this host.
- Allow EE traffic from branch office zone C to an EE service running on this host, using a dynamic VPN with strong authentication and encryption. Only one host behind the security gateway (branch office zone C) will be able to send EE traffic.

**Guideline:** In most cases, EE hosts should not be located behind a security gateway that is behind a NAT. Instead, a host-to-host Security Association should be negotiated for each EE host.

In “Steps for configuring the branch office model: Part 1 (host-to-gateway with IPSec)” on page 987, the VPN was brought up when the z/OS stack initialized by setting the AutoActivate parameter to Yes on
the LocalDynVpnRule statement. In this scenario, the hosts behind the gateway do not have public addresses that can be configured in the policy. Therefore, initiation from host 9.3.3.3 to the security gateway 9.5.5.5 becomes ambiguous because the IP address of the remote data endpoint is unknown. z/OS does not allow initiation of a UDP-encapsulated tunnel mode Security Association to a security gateway. The Security Associations between the security gateway 9.5.5.5 and host 9.3.3.3 must be initiated by the security gateway, with host 9.3.3.3 acting as responder.

- Allow normal FTP traffic from branch office zone C to an FTP server running on this host, using a dynamic VPN with strong authentication and encryption. In “Steps for configuring the branch office model: Part 1 (host-to-gateway with IPSec)” on page 987, the VPN was activated by an administrator from the z/OS UNIX command line. Again, z/OS does not allow initiation of a UDP-encapsulated tunnel mode Security Association to a security gateway. The Security Associations between the security gateway and host 9.3.3.3 must be initiated by the security gateway, with host 9.3.3.3 acting as the responder.

- Peers authenticate themselves using the pre-shared key method.

**Procedure**

Perform the following steps to meet these requirements and configure the branch office with NAT model:

1. Determine the number of zones to be protected.
   The branch office represents one zone, zone C.
2. For each zone, determine what services are allowed and define an IpService block for each wanted service.
   Services are defined by their protocols and the well-known ports that they use.

   The definitions that describe FTP traffic can be combined in an IP service group. Typically, FTP clients use passive mode (PASV) or extended passive mode (EPSV) to connect to the FTP server when the client is behind a NAT. For more information on active and passive mode FTP, see “Considerations for IPSec-encapsulated FTP traffic when traversing a NAT” on page 1009.

   The range of server ports specified for the data connection reflects the port range specified for PASSIVEDATAPORTS in the server’s FTP.DATA file. For more information on PASSIVEDATAPORTS, see z/OS Communications Server: IP Configuration Reference.

   The following definitions show the services required for the server for PASV or EPSV:

   ```
   IpServiceGroup       FTPServer
     { 
       IpService       FTPServer-Control
         { 
           SourcePortRange       21
           Protocol              tcp
           Direction             bidirectional InboundConnect
           Routing               local
           SecurityClass         0
         } 
       IpService       FTPServer-Data-Passive
         { 
           SourcePortRange       50000-50200
           Protocol              tcp
           Direction             bidirectional InboundConnect
           Routing               local
           SecurityClass         0
         } 
     } 
   
   The traffic pattern for Enterprise Extender can be defined in one IpService block as follows:

   ```
   IpService       Enterprise-Extender
     { 
       SourcePortRange       12000-12004
       DestinationPortRange  12000-12004
       Protocol              udp
       Direction             bidirectional
       Routing               local
     } 
   ```
3. Determine the data endpoints to be protected.
   In this example, for the local host public IP address, 9.3.3.3, define the following statement:
   ```
   IpAddr                       PublicServerAddressA1
   {                           }
   Addr                       9.3.3.3
   ```

   In this case, the remote data endpoints are in the branch office's internal network. The z/OS NATT implementation does not require the coding of private addresses for the remote endpoints. Instead, the security gateway’s public address is treated as the remote data endpoint. The NAT is using a static mapping for the security gateway, so the public address of the gateway is specified. If the NAT was using dynamic mappings, the range of public IP addresses to which the security gateway could be mapped would need to be included in this definition.

   ```
   IpAddr                       BranchOfficeGateway
   {                           }
   Addr                       9.5.5.5
   ```

   This IP address is also needed to permit IKE traffic between the local public server and the remote branch office gateway.

4. Determine what level of security is needed between each set of data endpoints.
   In this example, strong authentication and encryption is needed for both EE and FTP traffic, so ESP authentication and ESP encryption are used. ESP must be used when NAT traversal support is being used.

5. Configure an IpGenericFilterAction statement for the level of security that is required (permit, deny, ipsec), including whether the connection should be logged, as follows:
   ```
   IpGenericFilterAction        ipsec
   {                           }
   IpFilterAction             ipsec
   ```

6. If IPSec is required between any two endpoints, take the following actions:
   a) Configure a key exchange policy that defines the parameters of the phase 1 negotiation as follows:

   1) Determine the required type and strength of protection for the phase 1 Security Association.
      In this example, SHA1 authentication is used because it is more secure than MD5, and AES encryption is used.

   2) Decide what type of peer authentication to use.
      In this example, pre-shared key authentication is specified in the requirements. Typically, the RSA signature method is preferable, given its numerous advantages, but for the purposes of example the pre-shared key method is used here. Because there is only one remote IKE peer in the branch office scenario (the remote security gateway), and because it is relatively simple to configure, pre-shared key authentication is a reasonable choice.

   3) Configure a KeyExchangeOffer statement that defines the parameters for the phase 1 negotiation as follows:

   ```
   KeyExchangeOffer             SHA1-AES-PSK
   {                           }
   HowToEncrypt               AES_CBC KeyLength 128
   HowToAuthMsgs              SHA1
   HowToAuthPeers             PresharedKey
   DHGroup                    Group14
   ```

   4) Decide whether NAT traversal will be allowed.
The AllowNat parameter on the KeyExchangePolicy and KeyExchangeAction statements enables the IKED to advertise NAT traversal support. For this model, allow NAT traversal support to be advertised for all phase 1 Security Associations by specifying Yes on the AllowNat parameter on the KeyExchangePolicy statement:

```plaintext
AllowNat Yes
```

For this model, use the NatKeepAliveInterval parameter default value, 20 seconds. When z/OS is behind a NAT, a NAT keep-alive timer is started, with the interval specified in NatKeepAliveInterval parameter on the KeyExchangePolicy statement. Because z/OS is not behind a NAT in this model, a NAT keep-alive is not kept regardless of the value specified or the default for NatKeepAliveInterval.

5) Determine the negotiation mode, Main or Aggressive.

Because security is a priority in the branch office with NAT model, the more secure Main mode is used for the phase 1 negotiation.

6) Configure a KeyExchangeAction statement as follows:

```plaintext
KeyExchangeAction
{  
  HowToInitiate main
  HowToRespondIKEv1 main
  KeyExchangeOfferRef SHA1-AES-PSK
}
```

7) Configure a LocalSecurityEndpoint statement and RemoteSecurityEndpoint statement as follows:

```plaintext
LocalSecurityEndpoint Public_IKED
{  
  Identity IpAddr 9.3.3.3
  LocationRef PublicServerAddressA1
}
```

```plaintext
RemoteSecurityEndpoint ZoneC_IKED
{  
  Identity Fqdn gateway.BO.example.com
  LocationRef BranchOfficeGateway
}
```

8) Configure a KeyExchangeRule statement that includes the two endpoints and the key exchange action, as follows:

```plaintext
KeyExchangeRule ZoneC_KeyExRule1
{  
  LocalSecurityEndpointRef Public_IKED
  RemoteSecurityEndpointRef ZoneC_IKED
  KeyExchangeActionRef Gold-PSK
  PresharedKey abracadabra
}
```

9) Include the KeyExchangeRule statement in the KeyExchangePolicy statement block, as follows:

```plaintext
KeyExchangePolicy
{  
  AllowNat Yes
  KeyExchangeRuleRef ZoneC_KeyExRule1
}
```

b) Configure an IpDynVpnAction statement defining the control of the phase 2 negotiation, as follows:

1) Determine the required type and strength of IPSec protection for the phase 2 Security Association.

   In this example, authentication is ESP HMAC_SHA1 and encryption is AES.

2) Determine whether tunnel or transport mode is required.
Tunnel mode is required when one of the security endpoints is a security gateway.

3) Configure an IpDataOffer statement that defines the parameters of the phase 2 negotiation, as follows:

```
IpDataOffer                  SHA-AES-Tunnel
{}                             
  HowToEncap                 tunnel
  HowToEncrypt               AES_CBC_KEYLENGTH 128
  HowToAuth                  ESP HMAC_SHA1
```

4) Determine which peer is allowed to initiate the negotiation.

In this scenario, the hosts behind the gateway do not have public addresses that can be configured in the policy. Therefore, initiation from host 9.3.3.3 to the security gateway 9.5.5.5 becomes ambiguous because the IP address of the remote data endpoint is unknown. z/OS does not allow initiation of a UDP-encapsulated tunnel mode Security Association to a security gateway. The Security Associations between the security gateway 9.5.5.5 and host 9.3.3.3 must be initiated by the security gateway, with host 9.3.3.3 acting as responder.

5) Configure an IpDynVpnAction statement that defines the control information for the phase 2 negotiation, as follows:

```
IpDynVpnAction               Gold-TunnelMode
{}                             
  Initiation                 remoteonly
    InitiateWithPfs          group2
    AcceptablePfs            group2
  IpDataOfferRef             SHA-AES-Tunnel
```

c) Decide how the Security Association is activated.

1) Only remote initiation of the Security Association is allowed, as specified for the Initiation parameter on the Gold-TunnelMode IpDynVpnAction statement. No LocalDynVpnRule or IpLocalStartAction statements are needed.

2) Create an IpFilterRule statement that allows IPSec traffic (ESP), or set the global IpFilterPolicy statement parameter PreDecap to off.

In this example, PreDecap off is used in the IpFilterPolicy statement.

7. Define an IpFilterRule statement for each set of data endpoints.

The rule should include the services that are allowed (one IpService statement for each allowed service), and the level of security that is required (a reference to the IpGenericFilterAction statement). If IPSec is required, create an IpFilterRule statement that allows IKE traffic (UDP, port 500 and 4500). See the IpAddr and IpAddrSet statements configured previously.

```
IpFilterRule                 Rule1C
{}                             
  IpSourceAddrRef            PublicServerAddressA1
  IpDestAddrRef              BranchOfficeGateway
  IpServiceRef               IKE-local-500
  IpServiceRef               IKE-local-4500
  IpGenericFilterActionRef   permit

IpFilterRule                 Rule2C
{}                             
  IpSourceAddrRef            PublicServerAddressA1
  IpDestAddrRef              BranchOfficeGateway
  IpServiceRef               Enterprise-Extender
  IpServiceGroupRef          FTPServer
  IpGenericFilterActionRef   ipsec
  IpDynVpnActionRef          Gold-TunnelMode
```

8. Define an IpFilterGroup statement for each zone and include the IpFilterRule statements that belong to that zone.

10. Include all configured statements in the stack-specific IP security configuration file.

Results

The following policy is the complete IP security policy for traffic from the local secure server to zone C, assuming that the reusable statements are included in the common IP security configuration file:

```
#-------------------------------------------------------
# Filter Policy for Secure Server
#-------------------------------------------------------
IpFilterPolicy
{
  PreDecap                   off
  FilterLogging              on
  AllowOnDemand              no
  IpFilterGroupRef           ZoneC
}

#-------------------------------------------------------
# KeyExchange Policy for Secure Server
#-------------------------------------------------------
KeyExchangePolicy
{
  AllowNat                   Yes
  KeyExchangeRuleRef         ZoneC_KeyExRule1
}

########################################################

  RemoteSecurityEndpointRef   ZoneC_IKED
  KeyExchangeActionRef        Gold-PSK
}
```
Steps for configuring the branch office model: Part 2 (gateway-to-gateway with IPSec)
The branch office model part 2 is similar to the branch office model part 1. Here, there are multiple data endpoints on both the local side and the remote side, but only one pair of security endpoints, one local and one remote.

Before you begin
It is not likely that the z/OS system will function strictly as a router or a firewall at the network perimeter, but it is possible to configure the z/OS system to provide the IPSec functionality that many secure gateway devices provide. This topic includes instructions on how to configure a scenario in which the z/OS system is routing network traffic from inside the internal network. This functionality is similar to the functionality that is provided by the branch office gateway in “Steps for configuring the branch office model: Part 1 (host-to-gateway with IPSec)” on page 987. Here, there are multiple data endpoints on both the local side and the remote side, but only one pair of security endpoints, one local and one remote.

In this example, assume that the local z/OS system is acting as a secure gateway for hosts on an internal network A, and tunneling the IPSec-protected traffic to a remote secure gateway for subnetwork C. The following list summarizes the requirements for this example:

- Permit IKE negotiations between the two security gateways, the secure local host and the secure remote gateway for subnetwork C.
- Permit traffic from the internal network to the internal interface on the secure local host.
- Add IPSec protection to any traffic that flows between the two secure gateways.

In this scenario, the z/OS system is a secure forwarding agent for the internal hosts, rather than a data endpoint. Traffic from the internal hosts that is destined for the remote network first comes to the secure local gateway in the clear. Before it is sent out to the remote network, it is IPSec encapsulated. The process is reversed for traffic that comes from the remote network. Traffic that comes from the remote network to the local secure gateway is IPSec decapsulated on the local secure host and forwarded to the internal host in the clear.

Procedure
Perform the following steps to meet the above requirements and configure part 2 of the branch office model.

1. Permit IKE negotiations between the two secure gateways.
   UDP port 500 traffic must be allowed for IKE negotiations.

<table>
<thead>
<tr>
<th>IpFilterRule                  Rule1AtoC</th>
</tr>
</thead>
<tbody>
<tr>
<td>IpSourceAddrRef                  PublicServerAddressA1</td>
</tr>
<tr>
<td>IpDestAddrRef                    BranchOfficeGateway</td>
</tr>
<tr>
<td>IpServiceRef                     IKE</td>
</tr>
<tr>
<td>IpGenericFilterActionRef        permit</td>
</tr>
</tbody>
</table>

   The bidirectional keyword on the IpService statement creates two filter rules, one inbound and one outbound. Expansion of this IpFilterRule statement is shown in Table 51 on page 1003.

2. Permit traffic from the internal network to the internal interface on the secure host.

<table>
<thead>
<tr>
<th>IpFilterRule                  Rule2AtoC</th>
</tr>
</thead>
<tbody>
<tr>
<td>IpSourceAddrSetRef               SubnetC</td>
</tr>
<tr>
<td>IpDestAddrSetRef                 InternalNetworkA</td>
</tr>
<tr>
<td>IpServiceGroupRef               All-traffic-routed</td>
</tr>
<tr>
<td>IpGenericFilterActionRef        permit</td>
</tr>
</tbody>
</table>

   The bidirectional keyword on the IpService statement creates two filter rules, one inbound and one outbound. Expansion of this IpFilterRule statement is shown in Table 51 on page 1003.
Table 51. Expanded filter rule for internal traffic

<table>
<thead>
<tr>
<th>Source</th>
<th>Destination</th>
<th>Routing</th>
<th>Direction</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>SubnetC</td>
<td>InternalNetworkA</td>
<td>Routed</td>
<td>Outbound</td>
<td>permit</td>
</tr>
<tr>
<td>InternalNetworkA</td>
<td>SubnetC</td>
<td>Routed</td>
<td>Inbound</td>
<td>permit</td>
</tr>
</tbody>
</table>

As required, traffic that enters the secure server from InternalNetworkA that is destined for SubnetC is permitted by the secure host as an inbound routed packet. Traffic that leaves the secure server from SubnetC destined for InternalNetworkA is permitted by the secure host as an outbound routed packet.

3. Add IPSec protection to any traffic that flows between the two secure gateways.

```
IpFilterRule                 Rule3AtoC
{                               
  IpSourceAddrSetRef         InternalNetworkA
  IpDestAddrSetRef           SubnetC
  IpServiceGroupRef          All-traffic-routed
  IpGenericFilterActionRef   ipsec-log
}
```

Expansion of this rule is shown in Table 52 on page 1003.

Table 52. Expanded filter rule for remote traffic

<table>
<thead>
<tr>
<th>Source</th>
<th>Destination</th>
<th>Routing</th>
<th>Direction</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>InternalNetworkA</td>
<td>SubnetC</td>
<td>Routed</td>
<td>Outbound</td>
<td>ipsec</td>
</tr>
<tr>
<td>SubnetC</td>
<td>InternalNetworkA</td>
<td>Routed</td>
<td>Inbound</td>
<td>ipsec</td>
</tr>
</tbody>
</table>

Traffic that leaves the secure server from InternalNetworkA that is destined for SubnetC is permitted with ipsec. Traffic that enters the secure server from SubnetC that is destined for InternalNetworkA is permitted with ipsec.

Additional topologies

There are alternative security models that might be suitable for particular networks. Each of these configurations is supported by z/OS IP security.

Cascaded tunnels

If there are multiple hops from data endpoint to data endpoint, there might be Security Associations between any two hosts along the path. For example, the data might be authenticated from a host to the secure gateway, then encrypted for transportation over the Internet, then possibly authenticated and encrypted from the second secure gateway to the host on the other side, as shown in Figure 124 on page 1004:
Nested tunnels

In a nested environment, data is encapsulated multiple times over multiple hops. If the local and remote hosts are both behind a secure gateway, there could be a tunnel-mode Security Association that carries the traffic from one secure gateway to the other. Meanwhile, a transport-mode Security Association could carry the traffic from one host to the other, end-to-end. In this case, the transport-mode Security Association is nested in the tunnel-mode Security Association. Data from the local host is encapsulated once when leaving the local machine, encapsulated again at the secure gateway, decapsulated at the other secure gateway, and decapsulated one final time at the remote host, leaving only the original packet.

Mobile users

Mobile users represent a unique security model, because their IP address is not fixed and can be unpredictable. Instead of selecting traffic based on remote IP address, the mobile user's IKE identity can be used to select traffic. IPSec protection is required so that the IKE identity is known. You configure this security model similarly to other security models that require IPSec protection, except that the peer’s remote identity is indicated on the RemoteIdentity parameter of the IpFilterRule statement, and the IpDestAddr parameter typically uses a wildcard value to indicate all addresses.

Multicast traffic

Multicast traffic can be protected by IPSec, but only manual tunnels are supported because the IKED supports negotiating dynamic tunnels with only a single peer rather than with a group of peers.
Multicast traffic is one-to-many (sent by individual nodes but received by multiple nodes) and is normally both sent and received; therefore, to use manual tunnels for multicast, you must use the same Security Parameter Index (SPI) and keys for inbound and outbound traffic. You must coordinate the SPI values and keys that are used with all multicast peers on the LAN segment. Also, because this manual tunnel is to be used to protect traffic with various source and destination addresses, you must specify any or any6 for the local and remote security endpoint locations. The following example shows AH authentication using the SHA algorithm, and ESP encryption using the DES algorithm.

```
IpManVpnAction tunnel-multicast
  {
    LocalSecurityEndpointAddr any
    RemoteSecurityEndpointAddr any
    HowToAuth AH HMAC_SHA1
      AuthOutboundSa 2700 0xa66e1b72e58a367ebd39d6d2daef84d5d9222cfe1
      AuthInboundSa 2700 0xa66e1b72e58a367ebd39d6d2daef84d5d9222cfe1
    HowToEncrypt DES
      EncryptOutboundSa 2701 0x3e6dcf72459ef551
      EncryptInboundSa 2701 0x3e6dcf72459ef551
    HowToEncap transport
  }

Requirement: You must define two filter rules for the multicast traffic. The first rule matches outbound multicast traffic, which has a unicast source address and a multicast destination address. The second rule matches inbound multicast traffic, which has a remote (destination) address that is unicast, and a local (source) address that is multicast. The addresses of the inbound rule are reversed from those that you might expect, because bidirectional rules are written from an outbound perspective. These rules are as follows:

```
IpFilterRule outbound-multicast
  {
    IpSourceAddrSetRef lan-home-address
    IpDestAddr 224.0.0.1
    IpServiceRef service-udp
    IpGenericFilterActionRef ipsec-nolog
    IpManVpnActionRef tunnel-multicast
  }
IpFilterRule inbound-multicast
  {
    IpSourceAddr 224.0.0.1
    IpDestAddr lan-subnet
    IpServiceRef service-udp
    IpGenericFilterActionRef ipsec-nolog
    IpManVpnActionRef tunnel-multicast
  }
```

It is possible to restrict the tunnel to the multicast address that is being used. Define separate tunnels for different multicast addresses and use the same SPI value (the combination of address and SPI makes the tunnel unique). Because the local system is expected to participate in both sending and receiving multicast messages, you must create two manual tunnels. The following example shows this approach. In this example, one endpoint address is known for each tunnel, so you specify that address for the particular security endpoint address.

```
IpManVpnAction tunnel-multicast-outbound
  {
    LocalSecurityEndpointAddr any
    RemoteSecurityEndpointAddr 224.0.0.1
    HowToAuth AH HMAC_SHA1
      AuthOutboundSa 2700 0xa66e1b72e58a367ebd39d6d2daef84d5d9222cfe1
      AuthInboundSa 2700 0xa66e1b72e58a367ebd39d6d2daef84d5d9222cfe1
    HowToEncrypt DES
      EncryptOutboundSa 2701 0x3e6dcf72459ef551
      EncryptInboundSa 2701 0x3e6dcf72459ef551
    HowToEncap transport
  }
IpManVpnAction tunnel-multicast-inbound
  {
    LocalSecurityEndpointAddr 224.0.0.1
    RemoteSecurityEndpointAddr any
    HowToAuth AH HMAC_SHA1
      AuthOutboundSa 2700 0xa66e1b72e58a367ebd39d6d2daef84d5d9222cfe1

IP security 1005
Tip: Configuration of manual tunnels for IPv6 multicast is similar. For specific examples of configuring this for OSPFv3 security, see “Considerations for IPv6 OSPF security” on page 871.

Configuration scenarios supported for NAT traversal

Communications Server can act as a host Security Association endpoint for UDP-encapsulated mode Security Associations that are negotiated to enable IPSec traffic to traverse a NAT. The partner company with NAT model and the partner company with NAPT model describe Communications Server’s host-to-host support. The branch office with NAT model describes Communications Server’s host-to-security gateway support.

Rule: Communications Server does not support acting as a security gateway endpoint for UDP-encapsulated tunnel mode Security Associations. This is different than the Communications Server support provided for tunnel mode Security Associations, where Communications Server can act as a security gateway, although Communications Server is not typically deployed in this manner.

The figures in the subtopics show z/OS configuration support for UDP-encapsulated Security Associations. A Security Association is negotiated by two IKE peers, with one initiating the negotiation and the other acting in responder mode. The location of the NAT, and the NAT’s functionality, affect which IKE peer can initiate the Security Association. A traditional dynamic NAT implementation requires outbound traffic to be sent first to create an address mapping, before inbound traffic can be accepted. The dynamic NAT can be creating one-to-one address mappings from a dynamic pool of public IP addresses, or creating many-to-one address port mappings using a single public IP address and a pool of port values. When an IKE responder is behind a NAT, the NAT’s address mapping must be static, allowing inbound traffic for the address to be received prior to outbound traffic being sent.

Host-to-host scenario 1 - z/OS-to-z/OS

Figure 126 on page 1007 shows a NAT in front of both z/OS hosts. A configuration with a NAT in front of only one of the z/OS hosts is supported as well. If there is a NAT device in front of the responder, the NAT’s address mapping must be static. If there is a NAT device in front of the initiator, the NAT’s address mapping can be static or dynamic. A dynamic mapping can use either one-to-one address translation or many-to-one address port translation (NAPT).
Either UDP-encapsulated transport mode or UDP-encapsulated tunnel mode can be negotiated in a z/OS host-to-z/OS host configuration.

**Rule:** The z/OS host is limited to acting in responder mode when the remote endpoint is behind a NAPT. The negotiation of the phase 1 and phase 2 Security Associations must be initiated by the client behind the NAPT. Data must be initiated by the client behind the NAPT.

**Host-to-host scenario 2 - z/OS-to-non-z/OS**

Figure 127 on page 1007 shows a NAT in front of the z/OS host and the non-z/OS host. A configuration with a NAT in front of only one of the hosts is supported as well. If there is a NAT device in front of the responder, the NAT’s address mapping must be static. If there is a NAT device in front of the initiator, the NAT’s address mapping can be static or dynamic. A dynamic mapping can use either one-to-one address translation or many-to-one address port translation (NAPT).

**Interoperability Considerations**

z/OS is typically used to provide a server function. The client initiates the phase 2 Security Association (SA) and data, with z/OS acting in the role of IKE responder and data responder. z/OS provides robust NAT traversal responder support, allowing it to interoperate with a variety of clients.

z/OS can also act as the initiator of the phase 2 SA and data. Potential incompatibilities exist in the following cases, depending on the support that the non-z/OS peer provides:

- Any IKEv2 tunnel mode phase 2 SA

  When z/OS initiates an IKEv2 tunnel mode phase 2 SA, it represents the data that is being protected by the SA with the following addresses:
- The local IP address as it appears in the home list. This address might be a private IP address if z/OS is behind a NAT.
- The public IP address of the client.

The phase 2 SA negotiation should succeed if the non-z/OS peer supports receiving a tunnel mode traffic specification that is using these IP addresses.

- IKEv1 phase 2 SAs that protect specific ports, protocols, or both

When initiating this type of phase 2 SA, z/OS represents the data being protected by the SA with the following addresses and values:

- The local IP address as it appears in the home list. This could be a private IP address if z/OS is behind a NAT.
- The client’s public IP address.
- The specific port and protocol values.

The Phase 2 SA negotiation should succeed if the non-z/OS peer supports receiving this specification.

- IKEv1 tunnel mode phase 2 SAs that protect all ports and protocols

When z/OS initiates this type of phase 2 SA, it does not explicitly include the IP addresses of the data being protected in the negotiation of the SA. This allows the non-z/OS peer to view the protected data in terms of the IP addresses that it understands, the public address of the remote endpoint and the private address of the local endpoint. The phase 2 SA negotiation should be successful.

If data is initiated from z/OS over the SA, the data packet contains the following addresses:

- The local IP address as it appears in the home list. This address might be a private IP address if z/OS is behind a NAT.
- The client’s public IP address.

If the non-z/OS peer supports receiving a packet with these IP addresses, the data flow should be successful. When z/OS receives data packets from the non-z/OS peer, z/OS sends packets that contain the IP addresses used by the peer.

**Host-to-security gateway scenario**

Figure 128 on page 1008 shows both the security gateway and the host behind a NAT. z/OS also supports acting in responder mode when only one endpoint (either the security gateway or the z/OS host) is behind a NAT. When there is a NAT device in front of the z/OS host (acting as responder), the address mapping of the NAT must be static. If there is a NAT device in front of the security gateway, the address mapping of the NAT can be static or dynamic. A dynamic mapping can use either one-to-one address translation or many-to-one address port translation (NAPT).

*Figure 128. z/OS in a host-to-security gateway configuration*

**Rule:** The z/OS host is limited to acting in responder mode in a host-to-security gateway configuration when a NAT is traversed. The phase 2 Security Association negotiation must be initiated by the security gateway. Data must be initiated by the client behind the security gateway.
Figure 128 on page 1008 shows the clients and the security gateway as separate devices. However, whenever a Security Association is negotiated to protect something other than a single IP address (for example, a range of IP addresses), that IKE daemon negotiating the Security Association is acting as a security gateway.

When the security gateway is behind a NAT, the individual hosts behind the NAT cannot be distinguished. If only one NAT address is available, all Security Associations negotiated between the security gateway (GW) and z/OS are negotiated using the NAT address, and have the same security characteristics. If multiple security characteristics are required to protect the traffic behind the security gateway, more NAT addresses are needed so that z/OS can locate different policies based on the NAT address.

**Considerations for IPSec-encapsulated FTP traffic when traversing a NAT**

FTP requires both a control connection and a data connection. For active-mode FTP, the client initiates the control connection and provides IP address and port information for the server to initiate the data connection. If the client is behind a NAT, the client provides its private IP address. The NAT updates the IP address in the FTP data for a packet that is not encapsulated; however, when you use IPSec encapsulation to secure your FTP connection, the NAT is unable to update the IP address in the FTP data.

**Rule:** When the FTP client is behind a NAT, you must use passive-mode FTP.

For passive-mode FTP, the client initiates the control connection. When a file transfer is to be started, the client sends a passive (PASV) command to the server. In response to the PASV command, the server provides the IP address and port information for establishing the data connection. The client is then able to initiate the data connection to the IP address and port.

When the FTP server is behind a NAT, the IP address provided in the PASV response is its private address. The NAT updates the IP address in the FTP data for a packet that is not encapsulated; however, when you use IPSec encapsulation to secure your FTP connection, the NAT is unable to update the IP address in the FTP data.

**Rule:** When the FTP server is behind a NAT, you must use extended passive-mode FTP.

Extended passive-mode FTP eliminates the IP address from the FTP data. The server provides the port for the data connection, and the client connects to the same IP address that was used for the control connection.

The z/OS FTP client and server support extended passive-mode FTP using the EPSV command. If you are using the z/OS FTP client and the FTP server that you are accessing does not support the EPSV command, you can configure the PASSIVEIGNOREADDR statement for the z/OS FTP client and use passive-mode FTP, which is widely supported. The PASSIVEIGNOREADDR statement directs the z/OS FTP client to ignore the IP address in the PASV reply, and to connect to the same IP address used for the control connection.

For more information about FTP, see Chapter 12, “Transferring files using FTP,” on page 637. For a sample FTP.DATA data set, or for information about the LOCSIte subcommand, see z/OS Communications Server: IP User’s Guide and Commands.

**Enterprise Extender considerations when traversing a NAT**

The implementation of Enterprise Extender (EE) requires that the EE connection endpoints be defined by unique static VIPA addresses. NAT functions are limited in the EE environment as follows:

- The NAT mapping must be a one-to-one address mapping. NAPT is not supported.
- Dynamic mappings are generally unreliable for an EE connection. A static mapping of internal IP address to external IP address should be defined when an EE endpoint is behind a NAT.
- When IPSec protection is added for EE traffic that traverses a NAT, only one host that is behind a security gateway that is behind a NAT will be able to send EE traffic. In most cases, EE hosts should not be located behind a security gateway that is behind a NAT. Instead, a host-to-host Security Association should be negotiated for each EE host.
**Additional configuration concerns for NAT traversal**

The following list contains some additional configuration concerns for NAT traversal:

- **When using NAT traversal**, z/OS views its own address as the one configured in the z/OS home list. If the z/OS host is behind a NAT, this address is a private address. Otherwise, it is the public address of the z/OS host.

  The z/OS implementation does not use private addresses in its configuration to describe the remote IKE peer or remote IP connection endpoint. z/OS views its IPSec peer and the remote IP connection endpoint as a public IP address. If a NAT is in front of the IPSec peer, the z/OS host perceives the IPSec peer and connection endpoint addresses to be that of the NAT.

- **For IKEv1 Security Associations**, you should not configure pre-shared keys in Main mode when multiple remote peers are behind a NAT and the peers do not map to unique RemoteSecurityEndpoint specifications. RFC 3947 states that pre-shared keys cannot be used with Main mode, unless group shared keys for all those behind the NAT are deployed. The use of group pre-shared keys is considered a security risk.

- If a NAT address is coming out of a dynamic NAT pool, addresses assigned to a host from the pool can be assigned any of the pooled addresses. In this case, there are additional considerations. When z/OS is the responder, the IPSec policy intended for a host must be broad enough to cover the entire range of IP addresses in the dynamic NAT pool. When z/OS is the initiator and the responder is behind a NAT, the identity of the target host can be ambiguous. Do not configure a z/OS host to initiate to an ambiguous target host.

- When a remote security endpoint is behind a NAT, its identity must be unique. During a phase 1 negotiation, the remote security endpoint sends its identity in an ID payload. The IKE daemon can manage multiple remote security endpoints using the same ID when those endpoints are not behind a NAT. However, when a remote security endpoint is behind a NAT, it must use a unique IKE identity.

- When the remote security endpoint is a security gateway behind a NAT or a host behind a NAPT, only TCP, UDP, and ICMP traffic is supported. ICMP traffic has limited support.

- z/OS allows traffic for a TCP connection to continue as long as the integrity of the connection can be verified. Two cases where z/OS can no longer verify the integrity of the connection are:
  
  - Adding or removing IPSec protection for a TCP connection
    
    When a TCP connection traverses a NAT, the TCP connection must be restarted after a filter policy change that causes the connection’s traffic to change from IPSec-protected traffic to clear text, or from clear text to IPSec-protected traffic.
  
  - NAT IP address remapping
    
    If the peer’s IP address is remapped by a NAT due to a timeout or reboot of the NAT device, the TCP connection must be restarted.

**Configuring the IKE daemon**

This topic describes considerations and steps for configuring the IKE daemon.

The IKE daemon’s purpose is to manage dynamic IPSec tunnels and to provide a network management interface (NMI) for monitoring and controlling IP filtering and IPSec. The IKE daemon is not involved in the actual filtering, encapsulation, or decapsulation of packets. The IKE daemon is not required for the configuration or use of IP filters when no IpDynVpnAction statements are used. However, because the IKE daemon processes NMI monitoring requests, it must be running to gather monitoring data for IP filters, manual Security Associations, or dynamic Security Associations. To start the IKE daemon, it must be able to connect to the Policy Agent. For information about this requirement, see “Policy Agent considerations” on page 1012. For more information about the IPSec network management interface, see z/OS Communications Server: IP Programmer’s Guide and Reference.
Multiple TCP/IP stacks

A one-to-many relationship can exist between an instance of the IKE daemon and stacks configured with IPCONFIG IPSECURITY. A single instance of the IKE daemon can service all stacks configured with IPCONFIG IPSECURITY on a single z/OS image. Only one instance of the IKE daemon can run on a single z/OS image.

Each stack can be configured as a network security services (NSS) client. An NSS client makes use of network security services offered by the NSS server. For details about configuring an NSS server, see Chapter 18, “Network security services,” on page 1055.

“TCP/IP stack initialization access control” on page 142 describes a time interval during which limited stack access is available for stacks that have been configured for AT-TLS using the TCPCONFIG statement with the TTLS parameter. To enable the IKE daemon for a stack during this interval, the IKE daemon user ID must be permitted to the EZB.INITSTACK.sysname.tcpname resource profile. For examples of the security product commands needed to grant access to this profile, see member EZARACF in sample data set SEZAINST.

Run-time environment

The IKE daemon is a z/OS UNIX application, and it requires a z/OS UNIX file system such as z/OS File System. The IKE daemon can be started from an MVS started procedure, from the z/OS shell, with the AUTOLOG statement in the TCP/IP profile, or by using the COMMNDxx member of PARMLIB. The IKE daemon must be started by a RACF-authorized user ID, and it must be in an APF-authorized library. For more information about how to start the IKE daemon, see “Starting the IKE daemon” on page 1018.

The IKE daemon uses the MVS operator's console, syslogd, CTRACE, and STDOUT for its logging and tracing. The MVS operator's console and STDOUT are used for major events such as initialization, termination, and error conditions. Syslogd is used for logging events related to dynamic IPSec tunnel management. CTRACE is used for detailed tracing and debugging.

The IKE daemon uses a standard message catalog. The message catalog must be in the z/OS UNIX file system. The directory location for the message catalog path is set by the environment variables NLSPATH and LANG.

Language Environment run-time considerations

When starting the IKE daemon from a started or cataloged procedure, you should usually start the IKE daemon directly from the SEZALOAD data set using PGM=IKED. However, there is a situation where you might want to start the IKE daemon using BPXBATCH.

When the IKE daemon is started using PGM=IKED, the STDENV DD card, if used, is passed directly to the IKE daemon program. Language Environment does not get access to the STDENV environment variables. As a result, any Language Environment run-time options set in the STDENV DD data set using the _CEE_RUNOPTS= environment variable are ignored. In this case, Language Environment run-time options must be passed on the PARM= parameter and the options must be specified before any IKE daemon options. However, the PARM= statement allows a maximum of 100 characters. If the wanted Language Environment run-time options plus IKE daemon parameters exceeds 100 characters, consider using BPXBATCH to start the IKE daemon. When PGM=BPXBATCH is used, the Language Environment variable _CEE_RUNOPTS can be included on the STDENV DD card to specify run-time options in excess of 100 characters long.

IKE daemon configuration source information

The IKE daemon obtains configuration information from two sources.

• IKE daemon configuration file

The IKE daemon configuration file contains the IkeConfig statement. Parameters on the IkeConfig statement are global IKE daemon operational parameters. For details on the IKE daemon configuration file and the IkeConfig statement, see z/OS Communications Server: IP Configuration Reference.
The IKE daemon configuration file is read when the IKE daemon initializes and can be reread dynamically. For more information, see “Controlling the IKE daemon” on page 1019.

- Policy Agent

IP security policy includes dynamic IPSec tunnel configuration information required by the IKE daemon. The IKE daemon obtains IP security policy from the Policy Agent. The IKE daemon obtains IP security policy when connecting to the Policy Agent and whenever the Policy Agent informs the IKE daemon of a change in IP security policy. The IKE daemon connects only to stacks configured with IPCONFIG IPSECURITY, if there is an IP security policy defined for a stack. For details on configuring IP security policy, see “Configuring specific security models” on page 946.

**Policy Agent considerations**

The IKE daemon cannot perform management of dynamic IPSec tunnels until it has obtained IP security policy from the Policy Agent. While the Policy Agent is running, it can inform the IKE daemon of dynamic changes to IP security policy. After the IKE daemon has obtained an IP security policy, the Policy Agent can be stopped without impacting the IKE daemon. However, any changes to the IP security policy will not be detected until the Policy Agent is restarted, nor will IKE detect newly activated or reactivated stacks. The IKE daemon reconnects to the Policy Agent when the Policy Agent is restarted. For information about starting and monitoring policy related applications using the Policy Agent, see “Step 7: Configuring Policy Agent to automatically monitor applications” on page 792.

**Using network security services**

The IKE daemon allows a stack to be defined as a network security services (NSS) client. When a stack is defined as an NSS client, the IKE daemon uses at least one network security service on behalf of that stack. Network security services are provided by an NSS server. An NSS server provides a certificate service and a remote management service. For details about the configuration of an NSS server, see Chapter 18, “Network security services,” on page 1055.

The certificate service of the NSS server is used to create and verify digital signatures on behalf of an NSS client. Certificates for stacks that are configured to use the NSS certificate service must be on the key ring of the NSS server. For details about configuring the IKE daemon to use the NSS certificate service, see “Step 6: Setting up the IKE daemon for digital signature authentication (optional)” on page 1337.

**Restriction:** If you want the IKED to use a digital signature authentication method to negotiate an IKEv2 Security Association for a stack, the stack must be configured to use the NSS certificate service.

The remote management service of the NSS server enables the IP filter rules and Security Associations of an NSS client to be monitored and managed from the system on which the NSS server is executing. For details about using the `ipsec` command to monitor and manage NSS clients, see z/OS Communications Server: IP System Administrator's Commands. For details about using the IPSec NMI to monitor and manage NSS clients, see z/OS Communications Server: IP Programmer's Guide and Reference.

The NSS server does not need to be on the same system as the IKE daemon. The location of the NSS server is specified by the NetworkSecurityServer parameter and optionally by the NetworkSecurityServerBackup parameter of the IkeConfig statement. For additional details about the IkeConfig statement, see z/OS Communications Server: IP Configuration Reference.

The NssStackConfig statement in the IKE daemon configuration file is used to define a stack as an NSS client. The ServiceType parameter of the NssStackConfig statement identifies what network security services are to be used by a stack. When a ServiceType value Cert is specified, the NSS certificate service is used. When a ServiceType value RemoteMgmt is specified, the NSS remote management service is used. The ServiceType parameter can be specified multiple times. For complete details about the NssStackConfig statement, see z/OS Communications Server: IP Configuration Reference.

When a stack is configured to use the NSS remote management service, the NSS server can send the IKE daemon a request to switch between default IP filter policy and IP security filter policy. To change filter sets, the IKE daemon creates or deletes a specific marker file that the stack accesses. This marker file is the same marker file that is created or deleted by the `ipsec` command when the `ipsec -f reload` or...
**ipsec -f default** IP filter options are specified locally without the -z option. For details about the marker file, see z/OS Communications Server: IP System Administrator's Commands.

The ClientName parameter of the NssStackConfig statement associates an NSS client name with a stack. This is the name by which the NSS server knows the stack. The UserId parameter of the NssStackConfig statement associates the NSS client name with a user ID defined on the NSS server's system. The NSS server uses both the client name and user ID when checking SERVAUTH profiles to verify that an NSS client is authorized to request a specific action. For details about SERVAUTH profiles checked by the NSS server, see Chapter 18, "Network security services," on page 1055.

The AuthBy parameter of the NssStackConfig statement defines how the user ID associated with a stack that is acting as an NSS client is to be authenticated. This user ID can be authenticated using a password or a PassTicket. When a PassTicket is used, the application key is stored in the local external security manager database.

**Tip:** Using a PassTicket is more secure than specifying a password.

To store the application key in the local external security manager database, the secure signon function must be enabled and a PTKTDATA profile must be created. This key must be associated with an application ID of the NSSD. For specific information about enabling the secure signon function and defining profiles to be used by the single signon function, see z/OS Security Server RACF Security Administrator's Guide.

The following command is an example of a RACF command that you can issue to store the application key for the NSS server and NSS clients:

```
RDEFINE PTKTDATA NSSD SSIGNON(KEYMASKED(E001193519561977)) UACC(NONE)
```

Figure 129 on page 1014 shows a partial configuration for the IKE daemon on system SYSTEMA. The NetworkSecurityServer parameter on the IkeConfig statement specifies that the IKE daemon is configured to use network security services from an NSS server that is listening on IP address 9.1.1.1. One NssStackConfig statement is shown. The ClientName parameter associates stack STACK1 with an NSS client name SYSTEMA_STACK1. This is the name by which the NSS server knows this stack. The UserId parameter associates the client name with the user ID A1S1. The A1S1 user ID must be defined on the NSS server's system. Both the client name and user ID are used by the NSS server when verifying the authorization of an NSS client. The multiple ServiceType parameters indicate that the IKE daemon uses both the NSS certificate service and the NSS remote management service.
The IKE daemon requires that communication with the NSS server be protected using AT-TLS. During the AT-TLS handshake, the NSS server provides a certificate that can be used to authenticate its identity. The IKE daemon examines this certificate and verifies that the identity in the certificate matches the identity specified on the NetworkSecurityServer parameter of the IkeConfig statement.

The IKE daemon does not perform any SERVAUTH checks when processing an IPSec monitoring request or an IPSec management request from the NSS server. The NSS server performs SERVAUTH checks to make sure that the requester of an IPSec monitoring or management request is authorized. For details about the SERVAUTH requirements imposed by the NSS server, see z/OS Communications Server: IP Programmer's Guide and Reference.

The IKE daemon does perform a SERVAUTH check for the EZB.NETMGMT.sysname.sysname.IKED.DISPLAY profile when processing a local NMI request to display information about current NSS client state. For additional details, see z/OS Communications Server: IP Programmer's Guide and Reference.

**Certificate revocation checking**

Certificate revocation checking is applicable only to digital signature authentication methods. The RevocationChecking parameter in the IPSec policy file controls the level of certificate revocation checking that is performed during an IKE negotiation. The following three levels of revocation checking are supported:

- Strict
- Loose
- None

You can specify the RevocationChecking parameter on the KeyExchangePolicy statement and the KeyExchangeAction statement. For more information about the KeyExchangePolicy statement and the KeyExchangeAction statement, see z/OS Communications Server: IP Configuration Reference.
The native IKED certificate service does not support the retrieval and checking of certificate revocation information. When the IKED is configured to use the native IKE daemon certificate service, the RevocationChecking parameter is ignored.

The NSS certificate service does support the retrieval and checking of certificate revocation information in the form of certificate revocation lists (CRLs). For information about the NSS server requirements for retrieving CRLs, see “NSS server certificate revocation support” on page 1075. Ensure that these requirements can be met before you enable strict revocation checking in the IPSec policy file.

**Steps for configuring the IKE daemon**

The IKE daemon manages dynamic IPSec tunnels and provides a network management interface (NMI) for monitoring and controlling IP filtering and IPSec. Because the IKE daemon processes NMI monitoring requests, it must be running to gather monitoring data for IP filters, manual Security Associations, or dynamic Security Associations.

**Procedure**

Perform the following steps to configure the IKE daemon:

1. Create the IKE daemon configuration file.
   
   A sample configuration file is provided in /usr/lpp/tcpip/samples/iked.conf.
   
   The following search order is used by the IKE daemon to locate the configuration data set or file:
   
   a. If the environment variable IKED_FILE has been defined, the IKE daemon uses the value as the name of an MVS data set or z/OS UNIX file to access the configuration data.
   
   b. /etc/security/iked.conf
   
   You can specify statements in the configuration file using a variety of EBCDIC code pages. Use the IKED_CODEPAGE environment variable to specify the code page that you want to use. The default code page is IBM-1047.

2. Set the _BPX_JOBNAME environment variable (optional).
   
   When starting the IKE daemon from the z/OS shell, the environment variable _BPX_JOBNAME should be set. This enables a specific job name to be used when reserving ports for the IKE daemon. This name can also be used with the STOP or MODIFY console commands.
   
   For more information on _BPX_JOBNAME, see z/OS UNIX System Services Planning.

3. Reserve the ports.
   
   Update the PORT statement in PROFILE.TCPIP to reserve ports 500 and 4500 for the IKE daemon. Add the name of the member containing the IKE daemon cataloged procedure or the name as set using _BPX_JOBNAME:

<table>
<thead>
<tr>
<th>PORT</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>500 UDP IKED</td>
<td></td>
</tr>
<tr>
<td>4500 UDP IKED</td>
<td></td>
</tr>
</tbody>
</table>

4. Update the IKE daemon cataloged procedure.

   If the IKE daemon is to be started by a procedure, create the cataloged procedure by copying the following sample in SEZAINST(IKED) to your system or recognized PROCLIB. Specify IKE daemon parameters and change the data set names to suit your local configuration.

   //IKED     PROC
   //*
   //* IBM Communications Server for z/OS
   //* SMP/E distribution name: EZBIKPRC
   //*
   //* 5650-ZOS Copyright IBM Corp. 2005, 2013
   //* Licensed Materials - Property of IBM
   //* "Restricted Materials of IBM"
   //* Status = CSV2R1
   //*
   //* //IKED EXEC PGM=IKED,REGION=0K,TIME=NOLIMIT,
5. Authorize the IKE daemon to the external security manager.
   See “Step 3: Authorizing the IKE daemon to the external security manager” on page 1332.

6. Configure and start syslogd.
   The IKE daemon uses the local4 facility when writing messages to syslogd. For performance
   purposes, syslogd should use z/OS File System as its underlying file system. For more information on
   syslogd, see “Configuring the syslog daemon” on page 199.

   **Tip:** The system logging daemon (syslogd) can be configured to forward messages from the IKE
daemon to a syslogd on another host. For information about forwarding syslog messages to another
host, see z/OS Communications Server: IP Configuration Reference. When a stack is configured as an
NSS client, it can be advantageous to forward syslog messages from the IKE daemon to the syslogd
running on the NSS server's system. Configuring syslogd in this manner allows all IKE messages
relating to an NSS client to be in the same log file as the NSS server's messages.

7. Update the IKE daemon environment variables (optional).
   The following environment variables are used by the IKE daemon and can be tailored to a particular
installation:

   **IKED_CODEPAGE**
   Use the IKED_CODEPAGE variable to specify the EBCDIC code page to be used when reading the
   configuration file. For more information about IKE environment variables and the supported code
   pages, see z/OS Communications Server: IP Configuration Reference.

   **IKED_CTRACE_MEMBER**
   The IKED_CTRACE_MEMBER variable is used by the IKE daemon to locate a parmlib member for
   IKE daemon CTRACE customization. For more information on the TCP/IP services component
   trace for the IKE daemon, see z/OS Communications Server: IP Diagnosis Guide.

   **IKED_FILE**
   The IKED_FILE variable is used by the IKE daemon in the search order for the IKE daemon
   configuration file. For details on the search order used for locating this configuration file, see step
   “1” on page 1015.

8. Setup the IKE daemon for TCP/IP stack initialization access control (optional).
   See “Multiple TCP/IP stacks” on page 1011.
   See “Step 6: Setting up the IKE daemon for digital signature authentication (optional)” on page 1337.

10. Define AT-TLS policy to protect communication with an NSS server.

    The IKE daemon requires that communication between the NSS server and the IKE daemon be
    secured using Application Transparent Transport Layer Security (AT-TLS). If a stack is configured as
    an NSS client, AT-TLS rules must be defined to secure this communication. Enable AT-TLS processing
    for a stack by specifying the TTLS parameter on the TCPConfig statement in the TCP/IP profile.
    Specific AT-TLS policy is configured in Policy Agent configuration files. For details about enabling AT-
    TLS and configuring AT-TLS policy, see Chapter 20, “Application Transparent Transport Layer Security
    data protection,” on page 1093.

    **Tip:** Define AT-TLS policy such that only cipher suites requiring TLS encryption are exchanged with
    the NSS server. Failure to restrict the cipher suites to those requiring encryption can result in
    sensitive information flowing in the clear across an untrusted network.

    **Rule:** AT-TLS policy must be defined for each stack through which the IKE daemon communicates
    with the NSS server.

    A sample AT-TLS policy is located in /usr/lpp/tcpip/samples/pagent_TTLS.conf.

    **Rule:** The RemotePortRange value in the TTLSRule statement must include the value specified on the
    NetworkSecurityServer port parameter or the NetworkSecurityServerBackup port parameter in the
    IKE daemon configuration file.

11. Define IP filter policy to enable communication with an NSS server (optional).

    If a stack is configured as an NSS client, IP filter policy for that stack must be defined to enable this
    communication. The IKE daemon communicates with the NSS clients using the TCP protocol. By
    default, the NSS server listens on port 4159. The IKE daemon connects to the NSS client using an
    ephemeral port. Ephemeral ports are generally in the range 1024 – 65355.

    Two types of IP filter policy can be defined for a z/OS stack:

    • Default IP filter policy is defined in the TCP/IP profile. Updating default IP filter policy to permit
      communications between the IKE daemon and the NSS server is optional. Default IP filter policy is
      in effect only when IP security filter policy cannot be loaded or when the **ipsec -f default**
      command has been issued. For details about how to define default IP filter policy, see z/OS
      Communications Server: IP Configuration Reference.

    The following example of a default policy contains IPSECRule definitions that allow IKE daemon
    traffic with the NSS server:

    ```
    IPSEC LOGEnable
    ; Rule      SrcAddr DstAddr   Logging Protocol   SrcPort    DestPort     Routing Secclass
    ; OSPF protocol used by Omproute
    IPSECRule *   *         NOLOG   PROTO OSPF
    ; IGMP protocol used by Omproute
    IPSECRule *   *         NOLOG   PROTO 2
    ; DNS queries to UDP port 53
    IPSECRule *   *         NOLOG   PROTO UDP  SRCPort *  DESTport 53
    ; Administrative access
    IPSECRule *   9.1.1.2   LOG                                                SECCLASS 100
    ; IKE daemon access to the Network Security Server
    IPSECRule *   *         LOG     TCP        SRCPort *  DESTport 4159
    ; IKE daemon access to the Network Security Server
    IPSECRule *   *         LOG     TCP        SRCPort *  DESTport 4159
    ENDIPSEC
    ```

    **Rule:** The DESTport value in the filter rules must include the value specified for the
    NetworkSecurityServer port parameter or the NetworkSecurityServerBackup port parameter in the
    IKE daemon configuration file.
• IP security filter policy is defined in Policy Agent configuration files. IP security filter policy must be updated to permit communications between the IKE daemon and the NSS server. For details about how to define IP security policy files, see z/OS Communications Server: IP Configuration Reference.

The following example shows an IpFilterRule statement for IPv4, an IpFilterRule statement for IPv6, and an IpGenericFilterAction statement that allow the IKE daemon to communicate with the NSS server:

```
IpFilterRule             NssTrafficIPv4
{                        
  IpSourceAddr             all4
  IpDestAddr               all4
  IpService                
  {                        
    SourcePortRange        1024 65535
    DestinationPortRange   4159
    Protocol               tcp
    Direction              bidirectional OutboundConnect
    Routing                local
  }
  IpGenericFilterActionRef permit-nolog
}
IpFilterRule             NssTrafficIPv6
{                        
  IpSourceAddr             all6
  IpDestAddr               all6
  IpService                
  {                        
    SourcePortRange        1024 65535
    DestinationPortRange   4159
    Protocol               tcp
    Direction              bidirectional InboundConnect
    Routing                local
  }
  IpGenericFilterActionRef permit-nolog
}
IpGenericFilterAction     permit-nolog
{                          
  IpFilterAction           permit
  IpFilterLogging          no
}
```

**Rule:** The DestinationPortRange value on the IpService statement must include the value specified on the NetworkSecurityServer port parameter or the NetworkSecurityServerBackup port parameter in the IKE daemon configuration file.

---

### Starting the IKE daemon

After the necessary external security manager authorization has been defined (see “Step 3: Authorizing the IKE daemon to the external security manager” on page 1332), the IKE daemon can be started from an MVS procedure, from the z/OS shell, or using the AUTOLOG statement.

- You can start the IKE daemon procedure from the MVS operator console. A sample start procedure is provided in SEZAINST(IKED).
- You can start the IKE daemon from the z/OS shell by starting OMVS and then issuing the iked command.
- You can use the AUTOLOG statement to start the IKE daemon automatically during TCP/IP initialization by inserting the name of the IKE daemon start procedure into the AUTOLOG statement in the PROFILE.TCPIP data set:

```
AUTOLOG
  IKED
ENDAUTOLOG
```

**Tips:**

- When implementing multiple stacks enabled for IP security, adding an AUTOLOG statement for the IKE daemon might not be optimal. If the IKE daemon is listed in an AUTOLOG statement of a stack's
profile, the IKE daemon is cancelled if it is already running when that stack starts. In a multiple IP security stack environment, this could disrupt traffic on other IP security stacks. Use another method to automate starting the IKE daemon when the system is IPLed, such as using the COMMDNx member of PARMLIB. For more information about the use and configuration of the COMMDNx member of PARMLIB, see z/OS MVS Initialization and Tuning Reference.

– If you start the IKE daemon from the z/OS shell and you stop the shell environment from scrolling, then when the daemon needs to display data to the shell it might stop and wait indefinitely for the shell to scroll and make output buffer space available for the data.

When running from an MVS procedure, the environment variables can be set using the STDENV DD statement in the IKE daemon procedure. For information concerning the environment variables used by IKE daemon, see step “7” on page 1016 in “Steps for configuring the IKE daemon” on page 1015.

The /var/ike/iked.pid is a temporary IKE daemon pid file that the IKE daemon creates. This file contains the process ID of the current invocation of the IKE daemon.

Restrictions:

• If /var/ike/iked.pid is a symbolic link, it must have an owning UID or GID that matches the EUID or EGID that is assigned to the IKE daemon.

• If /var/ike/iked.pid is a hard link or the target of a hard link, users that are outside the owner or group of the directory in which /var/ike/iked.pid is stored cannot have write access to the directory. Additionally, write access to /var/ike/iked.pid must be limited to the owning UID or group, for example, --w--w---- permissions.

Stopping the IKE daemon

The IKE daemon can be stopped as follows:

• From MVS, issue:

```
STOP proName
```

If the IKE daemon was started from a cataloged procedure, `proName` is the member name of that procedure. If the IKE daemon was started from the z/OS shell and the environment variable _BPX_JOBNAME was set, `proName` is the same as _BPX_JOBNAME. If the IKE daemon was started from the z/OS shell and _BPX_JOBNAME was not set, `proName` is based on the userid. If the userid is 8-character long, the `proName` is the `userid`. If the `userid` is less than 8-character long, the `proName` is `useridX`, where X is the sequence number set by the system. To determine the sequence number, from the SDSF LOG window on TSO, issue:

```
/d omvs,u=userid
```

This command shows the programs running under this user ID. For more information on _BPX_JOBNAME, see z/OS UNIX System Services Planning.

• From a superuser ID in the z/OS shell, issue the kill command to the process ID (PID) associated with the IKE daemon. The IKE daemon PID is recorded in /var/ike/iked.pid.

Controlling the IKE daemon

You can control the IKE daemon from the operator's console using the MODIFY command. MODIFY commands are available to perform the following functions:

• Rereading the configuration file

The MODIFY proName,REFRESH command is used to reread the IKE daemon configuration file. Not all IkeConfig statement parameters can be updated using this command. For information on which parameters can be dynamically changed, see the parameter descriptions for the IkeConfig statement of the IKE daemon configuration file in the z/OS Communications Server: IP Configuration Reference.
• Displaying the configuration file parameters
  The MODIFY procname,DISPLAY command is used to display configuration values currently being used by the IKE daemon.

For more information on the MODIFY command, see z/OS Communications Server: IP System Administrator's Commands.

Verifying policy installation

This topic describes the console messages and commands that are used to verify policy installation.

Console messages

After the IP security policy has been configured, start the TCP/IP stacks, Policy Agent, and the IKED. A series of console messages is issued if the installation of IP security policy was successful.

The following console messages indicate that Policy Agent and IKE have completed initialization:

EZZ8432I PAGENT INITIALIZATION COMPLETE
EZD1046I IKE INITIALIZATION COMPLETE

The following console messages indicate that the processing of IP security policy is complete:

EZZ8771I PAGENT CONFIG POLICY PROCESSING COMPLETE FOR TCPCS : IPSEC
EZD1068I IKE POLICY UPDATED FOR STACK TCPCS

If there were errors in the configuration files, Policy Agent issues the following message to the console:

EZZ8438I PAGENT POLICY DEFINITIONS CONTAIN ERRORS FOR TCPCS : IPSEC

Look at the Policy Agent log to find and correct the error.

Displaying TCP/IP configuration

To display whether the TCP/IP stack is configured with IPCONFIG IPSECURITY, issue the netstat -f command and look for the following field in the IPv4 Configuration Table section:

IpSecurity: Yes

To display whether the TCP/IP stack is configured with IPCONFIG6 IPSECURITY, issue the netstat -f command and look for the following field in the IPv6 Configuration Table section:

IpSecurity: Yes

To display whether the TCP/IP stack is configured for Sysplex-Wide Security Associations, issue the ipsec -f display command. The DVIPSec field in the header of the command display shows whether or not the DVIPSEC keyword has been coded in the TCP/IP profile:

ipsec -f display | head -n 7
CS V1R12 ipsec Stack Name: TCPCS Tue Feb 16 10:52:03 2010
Primary: Filter Function: Display Format: Detail
Source: Stack Policy Scope: Current TotAvail: 137
Logging: 0n Predecap: 0ff DVIPSec: 1
NatKeepAlive: 20 FIPS140: No
Defensive Mode: Inactive

Displaying active filters with the ipsec command

Use the ipsec -f display command to display active filter rules, configured filter rules from IP security policy configuration files, and the default IP filter rules from the TCP/IP profile. The scope on the command, as indicated by the -c option, determines which source is queried:
-c policy
Shows IP filters as configured in the IP security policy configuration files.

- c profile
Shows default IP filters as configured in the TCP/IP profile.

- c current
Shows active IP filters in the stack. The active filters that are shown can be the default IP filters as defined in the TCP/IP profile, or IP filters as configured in the IP security policy configuration files, depending on which policy is active at the time the command is issued. The output of the display indicates the source of the current active filters.

The output of the command can be quite voluminous, so you might want to redirect the output of the display to a file.

The information in the report header of the report output indicates how many filters are active, and also indicates the source of the filters, whether from the default IP filter policy or the IP security policy from the Policy Agent.

```
  ipsec -f display

  Primary: Filter    Function: Display    Format: Detail
  Source: Stack Profile  Scope: Current  TotAvail: 14
  Logging: On  Predecap: Off  DVIPSec: Yes
  NatKeepAlive: 20  FIPS140: No

  Source: Stack Profile  Scope: Current  TotAvail: 14
  Logging: On  Predecap: Off  DVIPSec: Yes
  NatKeepAlive: 20  FIPS140: No
  Defensive Mode: Inactive
```

If the source field shows Stack Policy, the IP security policy is installed and active.

If the source field shows Stack Profile, the IP security policy is either not installed or the ipsec -f default command was issued. Either issue the ipsec -f reload command, or correct the IP security policy configuration.

Filter displays can be abbreviated to include only specific named rules. To view a named filter rule, use the -n option as follows:

```
  ipsec -f display -n Rule2Admin

  FilterName: Rule2Admin
  FilterNameExtension: 1

1022  z/OS Communications Server: IP Configuration Guide
Anchor filters and dynamic filters

After a Security Association is negotiated, the `ipsec -f display` command shows the addition of two dynamic filters that were created when the Security Association was created, corresponding to the inbound and outbound anchor filters. Dynamic filters are placed ahead of the anchor filters in the filter table, so dynamic filters are searched first when IP filtering is performed. In the following sample output, note that two dynamic filters have been added to the filter table subsequent to the activation of a phase 2 Security Association. The Type field indicates whether the filter is a dynamic anchor filter or a dynamic filter:

```
ipsec -f dis -n Rule2Admin
```

```

The inbound dynamic anchor filter protects TCP traffic from source address 9.6.0.0/16, source port any, to destination address 9.3.3.3, destination port 21. The inbound NATT anchor filter protects TCP traffic from source address 9.5.5.5, source port any, to destination address 9.3.3.3, destination port 21. The two inbound NATT dynamic filters also protect TCP traffic from source address 9.5.5.5, source port any, to destination address 9.3.3.3, destination port 21. However, the two NATT dynamic filters were negotiated for separate clients behind the security gateway. You can see that the first inbound NATT dynamic is for a host behind the security gateway using internal address 10.3.1.1 (value in the RmtIDpayload field).

The second inbound NATT dynamic is for a host behind the security gateway using internal address 10.3.2.2. The internal address of the data endpoint is what makes each NATT dynamic unique.

**NAT resolution filters**

Use the `-h` option on the `ipsec -f` command to display any NRFs associated with the displayed filters. After two clients behind the security gateway connect to host 9.3.3.3 using FTP, the NRFs might look like the following display. (The display is truncated to include only the NRFs.)

VpnActionName: Gold-TunnelMode
TunnelID: Y3
There are two NRF inbound/outbound entry pairs associated with the NATT anchor. In this example, two clients behind the security gateway have an FTP connection with host 9.3.3.3. The first outbound NRF entry is for:

source address 9.3.3.3, source port 21
destination address 9.5.5.5, destination port 34732
protocol TCP

The destination port is shown in the DestPort field. This value can be a translated value. The OrigRmtConnPort field indicates the original remote connection port, prior to remote port translation by Communications Server. In this example, the first outbound NRF shows that DestPort and OrigRmtConnPort are both 34732. For more information, see “Remote port translation” on page 906.

The second outbound NRF entry is for:

source address 9.3.3.3, source port 21
destination address 9.5.5.5, destination port 65535
protocol TCP

The original remote connection port (OrigRmtConnPort) is 34732. Because the values in DestPort and OrigRmtConnPort do not match, you can tell that the value was translated by Communications Server's remote port translation function. For more information, see “Remote port translation” on page 906.
The TunnelID field provides information on which phase 2 Security Association the traffic will be sent over. In this example, the phase two Security Associations are identified by the labels Y2 and Y3 respectively.

Displaying remote port translation with the ipsec command

As seen in “NAT resolution filters” on page 1031, the remote data endpoint is represented by the security gateway’s public IP address (9.5.5.5), not the client's IP address (10.3.1.1 or 10.3.2.2). Using the `ipsec -o display` command after the activation of two FTP connections in the branch office with NAT model, the port mappings are shown in the following display:

```
CS V1R12 ipsec Stack Name: TCPCS Tue Feb 16 11:43:55 2010
Primary: NATT Port Trans Function: Display Format: Detail
Source: Stack Scope: Current TotAvail: 2
RmtIpAddress: 9.5.5.5
Protocol: TCP(6)
TransRmtConnPort: 34732
OrigRmtConnPort: 34732
RmtInnerIpAddress: 10.3.1.1
***********************************************************************
RmtIpAddress: 9.5.5.5
Protocol: TCP(6)
TransRmtConnPort: 65535
OrigRmtConnPort: 34732
RmtInnerIpAddress: 10.3.2.2
***********************************************************************
2 entries selected
```

In both entries, you can see that the remote IP address (RmtIpAddress) value is 9.5.5.5, the IP address of the branch office gateway, the protocol is TCP (6), and the original remote connection port (OrigRmtConnPort) is 34732. The first entry shows that the translated remote connection port (TransRmtConnPort) is also 34732. The remote inner IP address contains the private address of the client behind the security gateway that initiated the connection, 10.3.1.1. The second entry shows that the remote connection port was translated to a value of 65535 (TransRmtConnPort), and that the client initiating the connection is using private IP address 10.3.2.2.

Table 53 on page 1035 details several places where one or both of the remote port values are displayed or used for a selection.

<table>
<thead>
<tr>
<th>Function</th>
<th>How remote port values are used</th>
<th>Which remote port, original or translated?</th>
</tr>
</thead>
<tbody>
<tr>
<td>Netstat displays of connection data, such as Netstat ALL/-A, Netstat ALLConn/-a, and Netstat Conn/-c</td>
<td>The Netstat command has many options to display connection information, including the remote port value. In some cases, the Netstat command takes a remote port value as a selector.</td>
<td>Translated remote port</td>
</tr>
<tr>
<td>Netstat display of the VIPA connection routing table (netstat VCRT/-V)</td>
<td>This command displays the remote port value in the sport or Source field, depending on the flavor of the report generated, and allows you to select based on port.</td>
<td>Translated remote port</td>
</tr>
<tr>
<td>Packet trace</td>
<td>Packet trace displays packet data as it was received or sent. If the packet is authenticated but not encrypted, the port is visible in the packet trace data.</td>
<td>Original remote port</td>
</tr>
</tbody>
</table>
### Table 53. Original and translated port values (continued)

<table>
<thead>
<tr>
<th>Function</th>
<th>How remote port values are used</th>
<th>Which remote port, original or translated?</th>
</tr>
</thead>
</table>
| **IPSecurity syslog messages:**  
  - EZD0814I packet permitted  
  - EZD0815I packet denied by policy  
  - EZD0821I packet denied, no tunnel  
  - EZD0822I packet denied, tunnel inactive  
  - EZD0832I packet denied by NAT traversal processing  
  - EZD0833I packet denied, tunnel mismatch  
  - EZD0836I packet permitted | For an inbound packet, the sport field in these messages contains a remote port value. For an outbound packet, the dport field in these messages contains a remote port value. These messages also have an origport field. | The sport and dport fields contain the translated remote port, and the origport field contains the original remote port. |
| **Defensive filtering syslog messages:**  
  - EZD1721I packet denied by defensive filter  
  - EZD1722I packet would have been denied by defensive filter | | |
| **Dynamic anchor, displayed with the `ipsec -f` command and the `ipsec -t` command** | The dynamic anchor that is configured in the Policy Agent configuration file can specify the remote port as a single port, a range of ports, or all ports. This specification of the remote port controls the range of ports that the original port can be translated to. Both the original port and the translated port for a connection will fit the range of ports coded. | The configured remote port value is displayed. A packet's original port is used to match on this rule. Both the original port and translated port are included in the remote port value displayed. |
| **NATT anchor, displayed with the `ipsec -f` command and the `ipsec -t` command** | The NATT anchor, which is created as a result of the Security Association negotiation, contains a specific remote port or all ports. | Original remote port if specific port displayed |
| **NATT dynamic, displayed with the `ipsec -f` command and the `ipsec -t` command** | The NATT dynamic, which is created as a result of the Security Association negotiation, contains a specific remote port or all ports. | Original remote port if specific port displayed |
| **NAT resolution filter (NRF), displayed with the `ipsec -f` command with the -h option** | The NAT resolution filter is a connection level filter, and contains both the translated remote port and the original remote port. | Translated remote port and original remote port. A packet's translated port is used to match on this rule. |
Displaying Security Associations with the ipsec command

Use the `ipsec` command to verify Security Associations.

Displaying IKE tunnel information with the ipsec command

Use the `ipsec -k display` command to display IKE tunnel information.

```
CS V1R12 ipsec  Stack Name: TCPCS  Tue Feb 16 11:48:25 2010
Primary: IKE tunnel  Function: Display  Format: Detail
Source: IKED  Scope: Current  TotAvail: n/a

```

The setting of the AllowNat field indicates whether or not NAT traversal support was advertised to the IKE peer. If AllowNat is Yes, the negotiation might or might not have detected a NAT. If the NATInFrntLclScEndPnt field is Yes, a NAT device was detected in front of the local security endpoint. If the NATInFrntRmtScEndPnt field is Yes, a NAT device was detected in front of the remote security endpoint.
Displaying IPSec tunnel information with the ipsec command

Use the `ipsec -y display` command to display IPSec tunnel information.

```bash
ipsec -y display -a Y39
```

The NAT Traversal Topology fields show additional information when a NAT was detected in the path between the IKE peers. The setting of the UdpEncapMode field indicates whether a UDP-encapsulated mode Security Association has or has not been negotiated. If NAT Traversal is supported by both IKE peers and one or more NATs are detected, UdpEncapMode is set to Yes. The RmtNATDetected field is Yes if a NAT is detected in front of the remote peer. The RmtIsGW field is Yes if the remote peer is acting as a security gateway.
Tip: Use the `-b` option of the `ipsec -y display` command to show the ports and protocols of the dynamic filter that are associated with the phase 2 Security Association. The following excerpt from the `ipsec -y display` using the `-b` option indicates a Telnet connection from a remote host:

<table>

</tr>
<tr>
<td>AssociatedFiltDestPort:</td>
<td>0</td>
</tr>
</tbody>
</table>

Displaying filter rules with the `pasearch` command

The configured IP filter rules and associated actions can also be viewed from the perspective of the Policy Agent. The `pasearch` command provides a way to view all Policy Agent configuration, of which IP security is a subset. In contrast to the information that is provided by the `ipsec` command, the detailed information that is provided by the `pasearch` command does not reflect the stack's active use of the IP security policy, but offers a relatively static view of configured IP security values that were generated from the IP security configuration file. For more information on displaying policy based networking information, see z/OS Communications Server: IP System Administrator's Commands.

Verifying filter action

To quickly determine which filter rule applies to a specific type of traffic, use the `ipsec` traffic test command (`ipsec -t`). This command returns all of the rules in the current filter table that match the given traffic type.

For example, to test which filter rule matches an incoming FTP connection request from remote IP address 9.1.1.2 to local IP address 9.1.1.1, issue the following command. The input values represent the remote address, local address, protocol, remote port, local port, direction, and security class of the packet:

```
$ ipsec -t 9.1.1.2 9.1.1.1 tcp 0 21 in 0
```

```

An incoming FTP connection request matches all of the rules shown in the example. The first rule that is returned does not always match a specific packet, depending on how much detail you provide as the input to the `ipsec -t` command. However, the Rule2Admin rule is the best match in this case, so the search for a matching filter ends there. The matching rule in this case is an ipsec rule, as indicated by the designation Dynamic Anchor. Therefore, IPsec processing is applied to this packet.

**Tip:** When using the `ipsec -t` command, provide as much detailed input as possible. The more detailed the input to the command, the more narrow the results of the search will be.

For detailed information about the use of the `ipsec` command, see z/OS Communications Server: IP System Administrator's Commands.

## Security Associations

This topic includes the following subtopics:

- Activating a Security Association
- Verifying the activation of a Security Association
- Verifying the use of an active Security Association
- Refreshing Security Associations
- Deactivating Security Associations

### Activating a Security Association

Negotiations can be initiated in one of four ways:

- **Remote activation**

  When a remote IKE peer initiates a negotiation with the local IKE daemon, no action is required. If the IP security policy has been configured correctly and is consistent with the policy of the remote IKE peer, a Security Association is established. No operator message is issued when a remote activation has occurred, but the syslog does contain a record of all IKE activity. The `ipsec -y display` command can also be used to view all of the active Security Associations.

- **On-demand activation**

  An on-demand Security Association is activated when some outbound traffic matches an ipsec rule that allows on-demand activation. The `ondemand` field of the filter display indicates whether or not on-demand activation is allowed for that rule.

- **Automatic activation**

  The local IKE daemon initiates a negotiation for an autoactivated Security Association when it connects to the TCP/IP stack. IKE also initiates a negotiation for an autoactivated Security Association when the `ipsec -f reload` command is issued, changing the active filter rule set from default IP filter rules to Policy Agent filter rules. No operator message is issued when an autoactivation has occurred, but the syslog does contain a record of all IKE activity. The `ipsec -y display` command can also be used to view all of the active Security Associations.

- **Command-line activation**

  The `ipsec` command can be used as follows to activate a Security Association that has been defined by a LocalDynVpnRule statement:

  ```
  ipsec -y activate -l ZoneC_VPN-EE1
  
  CS VIR12 ipsec Stack Name: TCPCS Wed Feb  3 16:02:05 2010
  Primary: Dynamic tunnel Function: Activate
  
  Selection Data Status
  ZoneC_VPN-EE1 Activating
  
  The output of the command indicates the status of the activation.
  ```
For detailed information about the use of the `ipsec` command, see z/OS Communications Server: IP System Administrator's Commands.

**Verifying the activation of a Security Association**

After a Security Association has been activated, it can be displayed with the `ipsec -y display` command. To view all active Security Associations, issue the following command:

```
ipsec -y display
```

You can use the `ipsec` command to view all of the active phase 1 Security Associations, or limit the report to a single phase 1 Security Association by using the `-a` option.

For detailed information about the use of the `ipsec` command, see z/OS Communications Server: IP System Administrator's Commands.

**Verifying the use of an active Security Association**

If `filter` logging is enabled for the selected `filter` rule, the log indicates whether a packet has been permitted with IPSec processing applied. Among the information available for a typical `filter` log entry are the rule name, the action, and the tunnel ID:

```
Feb 13 18:09:11 MVS175/TRMD     TRMD1    TRMD.TCPCS2[28]: EZD0814I Packet permitted: 02/13/2010 18:09:05.96 filter rule= Rule2Admin ext= 1 sipaddr= 9.1.1.2 dipaddr= 9.1.1.1 proto= tcp(6) sport= 3755 dport= 21 -= Interface= 9.1.1.1 (I) secclass= 255 dest= local len= 52 vpnaction= Silver-TransportMode tunnelID= Y58 ifcname= MPC4142L fragment= N
```

The `ipsec -y display` command also outputs a field with the number of bytes of traffic that have been protected by a particular Security Association.

For detailed information about the use of the `ipsec` command, see z/OS Communications Server: IP System Administrator's Commands.

**Refreshing Security Associations**

When a Security Association is refreshed, the encryption keys change. Refreshing a Security Association periodically prevents the keys from being compromised by an outside party. Phase 1 and phase 2 Security Associations are refreshed automatically, based on the lifetime or life size that was configured for IKEv2 or negotiated between the two IKE peers for IKEv1. When a lifetime expiration causes an IKEv2 phase 1 Security Association to refresh, the encryption key changes but the peer is not reauthenticated. Changing the key without reauthenticating the peer reduces CPU cost.

**Tip:** For phase 1, these parameters are specified in the KeyExchangeOffer statement. For phase 2, these parameters are specified in the IpDataOffer statement.

You can also refresh Security Associations from the z/OS UNIX command line, but this should be necessary only in exceptional conditions because the IKE daemon is normally responsible for refreshing the keys at configured intervals. Exceptional conditions might include the compromise of a key or the failure to receive an informational IKE message from a remote host. For both IKEv1 and IKEv2 Phase 1 Security Associations, refreshes from the z/OS UNIX command line include both reauthentication and re-keying.

**Phase 1**

Each phase 1 Security Association is identified by a tunnel ID, a number with a prefix of K. To manually refresh a phase 1 Security Association, issue the `ipsec -k display` command to find the tunnel ID. Then issue the `ipsec -k refresh` command for that ID as follows:

```
ipsec -k refresh -a K1
```

CS V1R12 ipsec    Stack Name: TCPCS    Tue Feb 16 11:48:04 2010
Primary: IKE tunnel    Function: Refresh

1044  z/OS Communications Server: IP Configuration Guide
Tunnel ID    Status
K1           Refreshing

For detailed information about the use of the `ipsec` command, see z/OS Communications Server: IP System Administrator's Commands.

**Phase 2**

Each phase 2 Security Association is identified by a tunnel ID, a number with a prefix of Y. To manually refresh a phase 2 Security Association, issue the `ipsec -y display` command to find the tunnel ID. Then issue the `ipsec -y refresh` command for that ID as follows:

```
ipsec -y refresh -a Y2
```

The phase 2 Security Association can also be identified by the local dynamic VPN rule with which it is associated, if one exists, as follows:

```
ipsec -y refresh -l ZoneC_VPN-EE1
```

For detailed information about the use of the `ipsec` command, see z/OS Communications Server: IP System Administrator's Commands.

**Deactivating Security Associations**

When a Security Association is deleted, all of the information that is stored in the Security Association is deleted from the TCP/IP stack and from the IKED, along with the dynamic filters that were created when the Security Association was created. After deletion, the Security Association is no longer available for use. Traffic that was protected by the old Security Association is denied until a new Security Association is subsequently activated.

When a parent phase 1 Security Association is deactivated, all of the associated phase 2 Security Associations are deleted as well. Be careful when deleting phase 1 Security Associations, because all traffic that uses the Security Association and its associated phase 2 Security Associations are dropped until new Security Associations can be negotiated.

- To delete a phase 1 Security Association and all of the phase 2 Security Associations it is protecting, issue the following command:

```
ipsec -k deactivate -a K1
```

- To delete all phase 1 Security Associations and all phase 2 Security Associations, use the `-a all` option as follows:

```
ipsec -k deactivate -a all
```

IP security 1045
To delete a phase 2 Security Association, issue the following command:

```
ipsec -y deactivate -a Y2
```

The n/a in the LocalDynVpnRuleName field indicates that no local dynamic VPN rule name is associated with this Security Association. The Security Association was either remotely activated or was activated on-demand.

To delete all phase 2 Security Associations, use the `-a all` option as follows:

```
ipsec -y deactivate -a all
```

For detailed information about the use of the `ipsec` command, see `z/OS Communications Server: IP System Administrator’s Commands`.

**Modifying active IP security policy**

This topic describes the effects of changes to security-related files and of issuing the `ipsec -f default` command.

**IP security policy files**

The IP security configuration files for a TCP/IP stack that has the IPSECURITY parameter defined can be modified while the stack is active in the following ways:

- Policy Agent configuration, including IP security, is updated at each configured refresh interval that is specified on the TcpImage statement for local policies or on the DynamicConfigPolicyLoad statement for remote policies. The default is 30 minutes.
- If Policy Agent was started with the `-i` option and the configuration files are stored in a z/OS UNIX file, changes to any of the configuration files are detected and updated dynamically without user intervention. The `-i` option has no effect when the policies are stored in remote configuration files on the policy server.
- Policy Agent configuration, including IP security, can be updated at any time by issuing the MODIFY PAGENT,REFRESH command or the MODIFY PAGENT,UPDATE command from the console of the policy client.

**Policy Agent image configuration files**

For an active TCP/IP stack with IPSECURITY defined, the following conditions apply:

- Changing the file name that is identified by an existing IpSecConfig or DynamicConfigPolicyLoad statement causes Policy Agent to update and install the IP security policy as defined in the new file. If the new IP security policy file contains errors, the policy is not updated and the existing IP security policy remains in effect.
- For local IP security policies, removing an existing IpSecConfig statement from a Policy Agent image configuration file activates the default IP filter policy.
- For remote IP security policies, removing the PolicyServer statement (or the PolicyType IPSec parameter on that statement) from a Policy Agent image configuration file activates the default IP filter policy, assuming that no local IP security policy is defined using the IpSecConfig statement.
Policy Agent main configuration file

For an active TCP/IP stack with IPSECURITY defined, removing an existing TcpImage statement from the Policy Agent configuration file has the following effects on IP security policy:

- Existing IP filters remain.
- Existing Security Associations remain.
- Traffic continues to flow in the same way it did before the TcpImage statement was removed, including IPSec-protected traffic.
- New Security Associations cannot be activated.
- Existing Security Associations cannot be refreshed and are deleted when the refresh period expires.

If the intent of removing the TcpImage statement is to remove IP filters from the stack, an alternative is to modify the IP security policy to install a filter rule that permits all inbound and outbound traffic. Also, before restarting the stack, the IPSECURITY parameter should be removed from the IPCONFIG statement of the relevant stack.

Active Security Associations and the ipsec -f default command

Any active Security Associations that were negotiated for IPSec-protected traffic are not deleted when the **ipsec -f default** command is issued. However, they are deleted if, while the default policy is in effect, any associated IP filter rules from the IP filter policy are deleted or modified in such a way that the filter rule no longer encompasses the scope of the Security Association. In that case, the Security Association will be deleted when the IP security policy is reloaded.

For example, Security Associations are not deleted by the following sequence of actions:

1. The **ipsec -f default** command is issued.
   - Security Associations remain active in the stack and in IKE, though unavailable for use.
2. No modification is made to the IP filter policy in the IP security configuration files.
   - Security Associations remain active in the stack and in IKE, though unavailable for use.
3. The **ipsec -f reload** command is issued.
   - Security Associations remain active in the stack and in IKE, and are available for use.

Security Associations are deleted by the following sequence of actions:

1. The **ipsec -f default** command is issued.
   - Security Associations remain active in the stack and in IKE.
2. The IpFilterRule statement that is associated with an active Security Association is deleted.
3. The IP security policy is updated by issuing the MODIFY PAGENT,REFRESH command from the console.
   - Existing Security Associations are deleted.
4. The **ipsec -f reload** command is issued.
   - Security Associations have been deleted.

In either case, Security Associations are never available for use when the default IP filter policy is in effect.
Displaying NSS client information

Use the NssStackConfig statement to configure a stack as an NSS client. Use the -w primary option on the **ipsec** command to determine which active stacks are configured as NSS clients, as well as their current status.

```
ipsec -w display

For complete details about the **ipsec** command, see z/OS Communications Server: IP System Administrator's Commands.
z/OS IP security supports Sysplex-Wide Security Associations (SWSA). In a sysplex environment, SWSA distributes IPSec Security Associations (SAs) to the target stacks of distributed DVIPAs. To enable this support for IPv4 DVIPAs, you must code IPCONFIG IPSECURITY in the TCP/IP profile and DVIPSEC in the IPSEC block. To enable this support for IPv6 DVIPAs, you must code IPCONFIG6 IPSECURITY, in addition to IPCONFIG IPSECURITY and DVIPSEC.

You should add DVLOCALFLTR, the DVIPSEC subparameter, to the IPSEC statement block of the TCP/IP profile when intra-sysplex traffic should be protected by security associations. DVLOCALFLTR enables IP filtering and IPSec protection of TCP traffic between a client and an IPv4 dynamic VIPA that are defined on the same TCP/IP stack, when the traffic is forwarded to another TCP/IP stack. When the DVLOCALFLTR parameter is configured, ensure that the IPSec policy accounts for all local TCP traffic with an IPv4 dynamic VIPA endpoint. Traffic that does not match a configured IP filter rule is denied.

Restrictions:

- The IKEv1 protocol cannot be used to negotiate a tunnel between a client and an IPv4 dynamic VIPA that are defined on the same TCP/IP stack. You must use the IKEv2 protocol to negotiate a tunnel to protect the traffic. Use HowToInitiate IKEv2 on the KeyExchangePolicy statement or a specific KeyExchangeAction statement to indicate that the IKEv2 protocol must be used when this system starts key negotiations.

- A tunnel cannot be negotiated if the source and destination IP addresses for client connections are the same dynamic VIPA. To help avoid this scenario, do not code a dynamic VIPA that can be used as a destination IP address on the TCPCONFIG TCPSTACKSOURCEVIPA or SRCIP statement in the TCP/IP profile.

In a sysplex environment, the IKE daemon can detect movement of a DVIPA to or from an IP security stack. To reestablish the Security Associations of a DVIPA, the DVIPSEC parameter must be specified in the TCP/IP profile of the stack from which the DVIPA is being moved and in the TCP/IP profile of the stack to which the DVIPA is being moved. For details about this movement, see “Sysplex-Wide Security Associations” on page 381. For information about the IPCONFIG, IPCONFIG6, and IPSEC statements that need to be added to the TCP/IP profile to configure this support, see z/OS Communications Server: IP Configuration Reference.

When a DVIPA is moved from one IP security stack in a sysplex to another IP security stack, and both stacks have the DVIPSEC option specified, an attempt is made to automatically reestablish Security Associations on the backup stack. The IKE daemon on the system that is assuming control of the DVIPA attempts to renegotiate new Security Associations to replace the ones that were on the system that previously owned the DVIPA. If these attempts fail due to configuration errors or connectivity errors, manual intervention might be required. Phase 1 Security Association or phase 2 Security Association negotiations that were in progress at the time of the DVIPA movement are lost. However, if these negotiations were for a refresh, a new negotiation is started in the process of assuming control of the DVIPA.

When a DVIPA is moved from one IP security stack in a sysplex to another IP security stack, and one or both stacks do not have the DVIPSEC option specified, the Security Associations that are associated with that DVIPA must be reestablished by issuing the **ipsec** command, on-demand activation, or by a peer initiation.

Guidelines:

- If a DVIPA is manually deleted and that address has no backup, the IKE daemon might not be able to terminate the tunnels in which the DVIPA is a security endpoint. To avoid this problem, use the **ipsec** command to deactivate the DVIPA's IKE tunnels before manually deleting the DVIPA.

- This support does not address the dynamic relocation of static filter rules and VPN policy definitions to the target system in the sysplex. It is up to you to ensure that the necessary filter rules and IP security policy definitions exist on all participating systems in the sysplex. If the necessary filter rules and IP security policy definitions do not exist, the IKE daemon might not be able to reestablish all Security...
Associations. For a description of the SWSA function, see “Sysplex-Wide Security Associations” on page 381.

**Rule:** Because the renegotiation of a Security Association after a DVIPA move requires the sysplex stack to initiate an IKE negotiation, the sysplex stack must be allowed to initiate. You must code the Initiation attribute on the IpDynVpnAction statement as `localonly` or `either`.

### NAT traversal and Sysplex-Wide Security Associations

The following topics describe Sysplex-Wide Security Associations (SWSA) in NAT traversal (NATT) configurations.

#### AES-GCM

When the AES-GCM combined-mode encryption and authentication algorithm is negotiated for an SA, decapsulation of all packets over that SA occurs on the distributing stack, and the decapsulated packets are forwarded to the target stack. In NAT traversal configurations, the target stack that is at a V1R12 or earlier release level expects the forwarded packets to be UDP-encapsulated packets. If a V1R12 target system is to participate in the workload distribution of traffic over a UDP-encapsulated mode SA that is using the AES-GCM algorithm, then the V1R12 PTF for APAR PM29788 must be applied because all the received packets are decapsulated on the distributing stack. APAR PM29788 enables a target stack to handle decapsulated packets from the distributing stack that were received over a UDP-encapsulated mode SA.

#### DVIPA recovery support

In NATT configurations where IKE can act only as the responder, sysplex distribution is possible but the recovery of the Security Associations when the DVIPA moves is not supported. There are two NATT configurations in which IKE can act only as the responder:

- When the IKE peer is a security gateway and a NAT is being traversed
- When the IKE peer is behind a NAPT

For more information about NATT configurations, as well as interoperability considerations, see “Configuration scenarios supported for NAT traversal” on page 1006.

When only one client behind a NAPT has negotiated a Security Association, it is not always possible for the server to detect whether one-to-one address translation or many-to-one address port translation (NAPT) is being done. When multiple clients have active Security Associations, the server can detect that port translation is being done. If z/OS cannot determine that a Security Association is negotiated with a remote peer behind a NAPT, the Security Association is treated as if it is being negotiated with a remote peer using one-to-one address translation.

When IKE is limited to only a responder role, the Security Association must be reestablished by peer initiation. The interoperability considerations for establishing an initial phase 2 Security Association are relevant to the renegotiation of the phase 2 Security Association due to the movement of a DVIPA. For example, a host-to-host UDP-encapsulated tunnel mode Security Association protecting specific protocols or ports that was initially initiated from a non-z/OS client might not be able to be renegotiated when the z/OS system assuming control of the DVIPA initiates the negotiation. In this case, the Security Association must be reestablished by peer initiation.

### FIPS 140 mode and Sysplex-Wide Security Associations

To enable FIPS 140 mode in a sysplex, you should enable FIPS 140 mode for all the TCP/IP stacks, IKE daemons, and network security services (NSS) daemons on all systems in the sysplex. If the FIPS 140 mode of the distributing TCP/IP stack in the sysplex is different than the FIPS 140 mode of the target TCP/IP stacks, distribution of some of the tunnels across the target TCP/IP stacks might not function as expected.

If the distributor is configured with FIPS 140 support, then all of the tunnels that it activates will adhere to the FIPS 140 restrictions (for example, DES encryption is not allowed). All target TCP/IP stacks can use the distributed tunnels and can process the distributed traffic, regardless of their FIPS 140 mode. The
targets that are configured without FIPS 140 support might not adhere to the strict cryptographic module boundaries as defined by FIPS 140, but the Security Association will be successfully activated and used.

If the distributor is not configured with FIPS 140 support, it might activate Security Associations that do not adhere to the FIPS 140 restrictions. The distributor can successfully distribute those associations to target TCP/IP stacks that are not configured in FIPS 140 mode. However, if the distributor distributes those associations to target TCP/IP stacks that are configured in FIPS 140 mode, the data flowing over connections to those stacks is discarded because the associated Security Association or tunnel is not installed.

The distributor and its backup can be configured differently with respect to the FIPS 140 mode. When a backup takes over from a distributor, all the IP security tunnels are renegotiated by the backup. The renegotiated tunnels operate at the FIPS 140 mode that is defined on the backup distributor. This can change the operation of the tunnels as they are distributed by the backup. If the distributor is configured with FIPS 140 support and its backup is not, the backup might activate Security Associations that do not adhere to the FIPS 140 restrictions and distribution of them might fail.

For more information about enabling FIPS 140 mode in a sysplex environment, see “Steps for configuring IP security to support FIPS 140 mode” on page 863.

Sysplex-Wide Security Associations in a mixed-level environment

This topic includes considerations for using Sysplex-Side Security Associations (SWSA) in a mixed-level environment.

Using encryption or authentication algorithms

IP security support includes encryption and authentication algorithms.

Restriction: Security Associations (SAs) and connections over SAs that use encryption or authentication algorithms that were introduced in V1R12 are not distributed to target stacks that are at a release prior to V1R12.

Using IPv6 DVIPAs

Support for Sysplex-Wide Security Associations (SWSA) for IPv6 DVIPAs is provided in z/OS V2R1 Communications Server or later releases.

- Encapsulated IPv6 traffic can be distributed to a target stack that is at the V2R2 or later release level.
- When an IPv6 DVIPA is taken over, SAs for that DVIPA can be reestablished by a backup stack that is at the V2R2 or later release level. A stack that is at release level V1R13 or earlier does not retrieve SA data associated with the IPv6 DVIPA from the coupling facility; the SAs are not renegotiated and the SA data remains in the coupling facility. If the original owning stack (V2R2 or later) regains ownership of the IPv6 DVIPA, SA data remaining in the coupling facility is used to attempt to reestablish the SAs. Do not use a stack that is at the V1R13 or earlier release level as a backup for an IPv6 DVIPA when there are SAs for the DVIPA.

Using IKEv2 tunnels

Support for the IKEv2 protocol was introduced in z/OS V1R12 Communications Server. Target stacks on a V1R12 system are able to support the capabilities of the IKEv2 protocol. Security Associations (SAs) that are negotiated using the IKEv2 protocol cannot be distributed to targets that are at a release level prior to V1R12. Connection requests that flow over those SAs will not be distributed to a target stack that is V1R11 or earlier. If you want the workload to be distributed across all the targets in the sysplex, all target stacks must be at release V1R12 or later.

During takeover of the SA, the IKE daemon on the backup system negotiates a new SA. The backup system must be at release V1R13 or later to negotiate the new SA using the IKEv2 protocol. If the backup stack is on a system that is V1R12 or earlier, the IKE daemon attempts to negotiate a new SA using the IKEv1 protocol.

Restrictions:
• Although a V1R12 backup system can recover a tunnel that was negotiated using IKEv2, any SA that is recovered will be converted to IKEv1 for the life of the SA.

• If you specify the HowToInitiate parameter with the value IKEv2 on a V1R12 backup stack, the IKE daemon on the backup system will fail to take over the SA. To prevent a failure, configure the HowToInitiate parameter with the value Main or Aggressive on the KeyExchangeAction statement or the KeyExchangePolicy statement.

AES-GCM and AES-GMAC in FIPS 140 mode

Security Associations (SAs) that are using the AES-GCM or AES-GMAC algorithms in FIPS 140 mode are not distributed when the distributing stack is at a V1R12 level. Connections over these SAs are handled on the distributing stack.

SAs that are using the AES-GCM or AES-GMAC algorithms in FIPS 140 mode can be distributed when the distributor is at a V1R13 or later level. However, the distributing stack distributes these SAs only to targets that are at a V1R12 level or later. Connection requests over these SAs are distributed only to target stacks that are at a V1R12 or later level. To ensure that the workload is distributed correctly, all target stacks should be at a V1R12 or later level.

Shadow Security Associations

When an IP security stack is the target of a DVIPA, it receives a copy (shadow) of any active Security Associations for the DVIPA. To display the shadow Security Associations, use the following command:

```
ipsec -y display -s
```

---

**Shadow Security Associations**

When an IP security stack is the target of a DVIPA, it receives a copy (shadow) of any active Security Associations for the DVIPA. To display the shadow Security Associations, use the following command:
Sample IP security policy files

A sample stack-specific policy is located in /usr/lpp/tcpip/samples/pagent_IPSec.conf.

A sample common policy is located in /usr/lpp/tcpip/samples/pagent_CommonIPSec.conf.
Chapter 18. Network security services

A network security services (NSS) server provides network security services for one or more security disciplines. Supported disciplines are IPSec, which is a set of services that supports IPSec and IKE processing, and XMLAppliance, which is a set of services for XML appliances. For the IPSec discipline, these services include the IPSec certificate service and the IPSec remote management service. For the XMLAppliance discipline, the NSS server supports the XMLAppliance SAF access service, the XMLAppliance certificate service, and the XMLAppliance private key service. For information about configuring the IKE daemon to act as an NSS IPSec client on behalf of a TCP/IP stack, see Chapter 17, “IP security,” on page 855.

Terms and concepts for network security services

The following terms and concepts apply to the information about network security services (NSS):

certificate bundle
An X.509 bundle as defined in Section 3.6 of RFC 5996, Internet Key Exchange Protocol: IKEv2. A certificate bundle can contain multiple DER encoded certificates and certificate revocation lists (CRLs). You can use the certbundle command to create a certificate bundle.

Certificate revocation list (CRL)
A time-stamped list of revoked certificates that is signed by a certificate authority.

CRLDistributionPoints
An optional X.509 certificate extension that identifies one or more locations where the CRL for a certificate is.

hash and URL encoding
A certificate payload encoding that includes the hash of a certificate or bundle and the URL that identifies where that certificate or bundle can be retrieved from an HTTP server.

IPSec certificate service
A service for NSS IPSec clients that provides IPSec digital signature and verification services.

IPSec discipline
A set of services provided to an NSS IPSec client. The services are the IPSec certificate service and the IPSec remote management service.

IPSec remote management service
A service for NSS IPSec clients that provides remote IPSec management capability.

Network security services (NSS)
A set of services that performs security enforcement or management. The services are provided in groupings called security disciplines.

NSS client
A client that requests network security services from an NSS server.

NSS daemon (NSSD)
The z/OS UNIX daemon that implements the NSS server functionality.

NSS IPSec client
An NSS client that is using the IPSec discipline. The z/OS IKE daemon can act as an NSS IPSec client for one or more TCP/IP stacks.

NSS server
Provides network security services for one or more NSS clients.

NSS XMLAppliance client
An NSS client that is using the XMLAppliance discipline.

security discipline
A specific grouping of network security services.
trust chain
The signing sequence of certificates for any particular certificate back to a root certificate authority.

XML appliance
A network appliance that processes XML messages efficiently and securely. XML appliances often offload XML parsing and transformations from host systems and implement a variety of XML security features.

XMLAppliance certificate service
A service for NSS XMLAppliance clients that provides key ring listing and certificate retrieval capability.

XMLAppliance discipline
A set of services provided to an NSS XMLAppliance client. The NSS server supports the XMLAppliance SAF access service, the XMLAppliance certificate service, and the XMLAppliance private key service.

XMLAppliance private key service
A service for NSS XMLAppliance clients that provides private key retrieval of private keys that are not protected by Integrated Cryptographic Service Facility (ICSF), RSA signature generation using ICSF-protected private keys, and RSA message decryption using ICSF-protected private keys.

XMLAppliance SAF access service
A service for NSS XMLAppliance clients that provides SAF user authentication and access control capability.

For additional IP security-related terms, see Chapter 17, “IP security,” on page 855.

Network security services overview
Network security services (NSS) includes services that perform security enforcement or management. As shown in Figure 130 on page 1056, NSS includes services provided by the NSS IPSec discipline and NSS XMLAppliance discipline. Each discipline includes a subset of services provided by NSS and is intended for use by a specific type of NSS client.

NSS IPSec discipline overview
The NSS IPSec discipline includes the NSS IPSec certificate service and NSS IPSec remote management service.
The NSS server provides the NSS IPSec certificate service to perform digital signature and verification operations on behalf of an NSS IPSec client. The NSS IPSec certificate service is used by an NSS IPSec client during a phase 1 negotiation when digital signature authentication is required. Certificates and private keys for all NSS IPSec clients are stored on a single key ring. The NSS server must have access to this key ring and must have access to the certificates and private keys on this key ring. When providing the NSS IPSec certificate service, the NSS server consults SERVAUTH profiles to verify that an NSS IPSec client is authorized to access the certificates that are involved. For details about these profiles, see step “8.d” on page 1061 and step “8.e” on page 1061, under “Steps for authorizing resources for NSS” on page 1058.

The NSS server uses the NSS IPSec remote management service to request IPSec monitoring data from an NSS IPSec client and to make IPSec control requests to an NSS IPSec client. Control requests include the ability to activate, deactivate, or refresh a Security Association, and to switch between default IP filter policy and IP security filter policy. Use the `ipsec` command and the IPSec network management interface (NMI) to make these requests. For details about the `ipsec` command, see z/OS Communications Server: IP System Administrator's Commands. For details about the IPSec NMI, see z/OS Communications Server: IP Programmer's Guide and Reference.

**NSS XMLAppliance discipline**

The NSS XMLAppliance discipline includes the NSS XMLAppliance SAF access service, the NSS XMLAppliance certificate service, and the NSS XMLAppliance private key service.

An NSS XMLAppliance client uses the NSS XMLAppliance SAF access service to perform SAF user authentication and access control checks. The NSS server consults SERVAUTH profiles for access control checks. For details about these profiles, see step “8.d” on page 1061 and step “8.e” on page 1061, under “Steps for authorizing resources for NSS” on page 1058.

The NSS XMLAppliance certificate service enables an NSS server to provide a list of authorized certificates on its key ring. Those certificates can then be retrieved on behalf of an NSS XMLAppliance client. Certificates for all NSS XMLAppliance clients are stored on a single key ring. The NSS server must have access to this key ring and must have access to the certificates on this key ring. When the NSS server provides the NSS XMLAppliance certificate service, it consults SERVAUTH profiles to verify that an NSS XMLAppliance client is authorized to access the certificates involved. For details about these profiles, see step “8.d” on page 1061 and step “8.e” on page 1061, in “Steps for authorizing resources for NSS” on page 1058.

An NSS XMLAppliance client uses the NSS XMLAppliance private key service to retrieve authorized private keys stored in the SAF database of the NSS server. The private key service also enables the NSS server to perform RSA signature and RSA decryption operations using private keys protected by Integrated Cryptographic Service Facility (ICSF) on behalf of an NSS XMLAppliance client. An NSS XMLAppliance client can use a retrievable private key to sign and decrypt XML messages locally. XML appliances that are in less-trusted network zones can use a centralized NSS server to perform critical RSA operations using ICSF-protected private keys on behalf of the appliance. Certificates and private keys for all NSS XMLAppliance clients are stored on a single key ring. The NSS server must have access to this key ring and must have access to the certificates and private keys on this key ring. Retrieval of the private key is not allowed if the private key is stored in the ICSF public key data set (PKDS). When providing NSS XMLAppliance private key service, the NSS server consults SERVAUTH profiles to verify that an NSS XMLAppliance client is authorized to access the certificates and associated keys involved. For details about these profiles, see step “8.d” on page 1061, step “8.e” on page 1061, and step “8.g” on page 1062 under “Steps for authorizing resources for NSS” on page 1058.

**Preparing to provide network security services**

Before network security services can be provided, authorization to several resources must be defined to the external security manager. This topic also includes NSS server certificate label naming considerations, an NSS client authorization example, information on configuring and controlling the NSS server, and recovery considerations.
Steps for authorizing resources for NSS

Before network security services can be provided, authorization to several resources must be defined to the external security manager.

Before you begin
RACF is used as the external security manager in the following examples. RACF commands shown in these examples are also provided in the EZARACF member of the SEZAINST data set. In these examples, it is assumed that the NSS server is running under the user ID NSSD.

Procedure
Perform the following steps to authorize access to the appropriate resources:

1. Define and authorize the NSSD user ID.
   The NSS server is a z/OS UNIX application that you can start from the z/OS UNIX shell or from an MVS started procedure. Before starting the NSS server, you must define the NSSD user ID to the external security manager with UID 0. If you start the NSS server from an MVS started procedure, the NSSD user ID must also be authorized to the STARTED class.
   Issue the following commands:

   ```shell
   ADDUSER NSSD DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(0) HOME('/'))
   RDEFINE STARTED NSSD.* STDATA(USER(NSSD))
   SETROPTS RACLIST(STARTED) REFRESH
   SETROPTS GENERIC(STARTED) REFRESH
   ```

2. Permit the NSSD user ID to SYS1.PARMLIB.
   The NSS server uses the TCP/IP component trace (CTRACE) to perform service-level tracing. The default NSS server component trace parmlib member is stored in SYS1.PARMLIB. The NSSD user ID must be permitted to access SYS1.PARMLIB.
   Issue the following command:

   ```shell
   PERMIT SYS1.PARMLIB ID(NSSD) ACCESS(READ)
   ```

3. Define key ring controls.
   Certificates used by NSS clients are stored on a SAF key ring. The RACDCERT command is used to manage a RACF key ring. The IRR.DIGTCERT FACILITY class resource is used to control access to the RACDCERT command. If these controls do not already exist, they must be defined as follows:

   ```shell
   RDEFINE FACILITY IRR.DIGTCERT.ADD UACC(NONE)
   RDEFINE FACILITY IRR.DIGTCERT.ADDRING UACC(NONE)
   RDEFINE FACILITY IRR.DIGTCERT.CONNECT UACC(NONE)
   RDEFINE FACILITY IRR.DIGTCERT.GENCERT UACC(NONE)
   RDEFINE FACILITY IRR.DIGTCERT.GENREQ UACC(NONE)
   ```
   For details about these controls, see z/OS Security Server RACF Command Language Reference.

4. Give the user ID of the administrator that will manage the NSS server’s key ring appropriate access to manage the key ring.
   Issue the following commands:

   ```shell
   PERMIT IRR.DIGTCERT.ADD CLASS(FACILITY) ID(userId) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.ADDRING CLASS(FACILITY) ID(userId) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.CONNECT CLASS(FACILITY) ID(userId) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.GENCERT CLASS(FACILITY) ID(userId) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.GENREQ CLASS(FACILITY) ID(userId) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.LISTRING CLASS(FACILITY) ID(userId) ACC(CONTROL)
   ```
   If you will issue the RACDCERT command using the NSSD user ID, READ authority to the IRR.DIGTCERT.ADD, IRR.DIGTCERT.ADDRING, IRR.DIGTCERT.GENREQ, and IRR.DIGTCERT.LISTRING resources is sufficient. Authority requirements for the other resources

---

**1058** z/OS Communications Server: IP Configuration Guide
remain the same. If you will issue the RACDCERT command using a user ID other than the NSSD user ID, you must provide appropriate access for the NSSD user ID to its own key ring as follows:

<table>
<thead>
<tr>
<th>Command</th>
</tr>
</thead>
<tbody>
<tr>
<td>PERMIT IRR.DIGTCERT.LIST CLASS(FACILITY) ID(NSSD) ACC(READ)</td>
</tr>
<tr>
<td>PERMIT IRR.DIGTCERT.LISTRING CLASS(FACILITY) ID(NSSD) ACC(READ)</td>
</tr>
</tbody>
</table>

After you permit access to the various IRR.DIGTCERT resources, update the FACILITY class as follows:

<table>
<thead>
<tr>
<th>Command</th>
</tr>
</thead>
<tbody>
<tr>
<td>SETROPTS RACLIST(FACILITY) REFRESH</td>
</tr>
</tbody>
</table>

5. Optionally, permit the NSS server to the BPX.DAEMON FACILITY class profile.

For information concerning the use of the BPX.DAEMON profile, see “BPX.DAEMON FACILITY class profile” on page 37.

If you decide to use this profile, permit the NSS server user ID to this profile using the following command, where the *userid* value is the user ID under which the NSS server runs:

<table>
<thead>
<tr>
<th>Command</th>
</tr>
</thead>
<tbody>
<tr>
<td>PERMIT BPX.DAEMON CLASS(FACILITY) ID(*userid) ACCESS(READ)</td>
</tr>
</tbody>
</table>

6. Enable the secured signon function.

The NSS server supports the use of PassTickets. To use this support, the secured signon function must be enabled, and at least one profile must be created for the NSS server.

The secured signon function of RACF is enabled by activating the PTKTDATA class as follows:

<table>
<thead>
<tr>
<th>Command</th>
</tr>
</thead>
<tbody>
<tr>
<td>SETROPTS CLASSACT(PTKTDATA)</td>
</tr>
<tr>
<td>SETROPTS RACLIST(PTKTDATA) REFRESH</td>
</tr>
</tbody>
</table>

Profiles in the PTKTDATA class control the use of the secured signon function by an application. A secured signon application key is associated with each profile. This key is stored in the external security manager's database. When RACF is used as the external security manager, this key is stored in a masked or encrypted state.

With RACF, you can use a secured signon application key that is controlled at the following levels:

- All users who need access to the application
- A specific RACF group of users who need access to the application
- A specific RACF user, when connected to a specific RACF group
- A specific RACF user

The application name NSSD must be used when defining the secured signon keys for the NSS server. The following example shows a RACF command that you can issue to assign a secured signon key that can be used by all NSS clients that are authenticating to the NSS server:

<table>
<thead>
<tr>
<th>Command</th>
</tr>
</thead>
<tbody>
<tr>
<td>RDEFINE PTKTDATA NSSD SSIGNON(KEYMASKED(E43E001193519561977)) UACC(NONE)</td>
</tr>
</tbody>
</table>

For specific information about enabling the secured signon function and defining profiles to be used by the single signon function, see z/OS Security Server RACF Security Administrator's Guide.

7. Define SERVAUTH profiles to authorize NSS clients to network security services.

These profiles are on the same system as the NSS server. Many of these profiles are constructed using the name of an NSS client. NSS clients must authenticate to the NSS server using a valid user ID and password, or a valid user ID and PassTicket. This user ID must be given access to the SERVAUTH profiles created on behalf of the NSS client.

For details about how to define the IKE daemon as an NSS client, see “Using network security services” on page 1012.

Perform the following steps to authorize NSS clients:

a. Define a SAF user ID representing an NSS client to the external security manager.
An NSS client must present valid credentials to the NSS server before accessing any services. Valid credentials include a user ID and password, or a user ID and PassTicket if secured signon is enabled. A SAF user ID representing an NSS client must be defined to the external security manager.

Issue the following command:

```
ADDUSER userid DFLTGRP(OMVSGRP) OMVS(UID(x))
```

**Rules:**

- Multiple NSS clients can use a single user ID. However, each NSS client must have a unique client name.
- A SAF user ID must have an OMVS segment with either AUTOID or a specific UID(x) defined for the NSSD to authenticate it as an NSS client.

**Guideline:** Because SAF user IDs are used to authorize a client to the NSS services, avoid sharing a single user ID across NSS disciplines.

b. If you choose to define an NSSD profile in the APPL class with UACC(NONE), issue the following command to authorize each SAF user ID to the NSSD application:

```
PERMIT NSSD CLASS(APPL) ID(userid) ACC(READ)
SETROPTS RACLIST(APPL) REFRESH
```

c. Authorize the user ID associated with an NSS client for each of the network security services it will use.

To authorize an NSS client to use a network security service, you must create a SERVAUTH resource profile for that service that represents the NSS client. The user ID associated with the NSS client must be permitted READ access to that profile. Table 54 on page 1060 shows the name of the SERVAUTH profile for each service, where sysname is the name of the z/OS system running the NSS server and clientname is the name by which the NSS server knows the NSS client.

<table>
<thead>
<tr>
<th>Service</th>
<th>SERVAUTH profile name</th>
</tr>
</thead>
<tbody>
<tr>
<td>IPSec certificate service</td>
<td>EZB.NSS.sysname.clientname.IPSEC.CERT</td>
</tr>
<tr>
<td>IPSec remote management</td>
<td>EZB.NSS.sysname.clientname.IPSEC.NETMGMT</td>
</tr>
<tr>
<td>XMLAppliance certificate</td>
<td>EZB.NSS.sysname.clientname.XMLAPPLIANCE.CERT</td>
</tr>
<tr>
<td>XMLAppliance private key</td>
<td>EZB.NSS.sysname.clientname.XMLAPPLIANCE.PRIVKEY</td>
</tr>
<tr>
<td>XMLAppliance SAF access</td>
<td>EZB.NSS.sysname.clientname.XMLAPPLIANCE.SAFACCESS</td>
</tr>
</tbody>
</table>

You can authorize the NSS client to a SERVAUTH profile using the following commands:

```
RDEFINE SERVAUTH profile_name UACC(NONE)
PERMIT profile_name (SERVAUTH) ID(nssclient) ACCESS(READ)
SETROPTS GENERIC(SERVAUTH) REFRESH
SETROPTS RACLIST(SERVAUTH) REFRESH
```

**Tip:** You can use a wildcard in the profiles to reduce the number of profile entries that must be defined.
d. Create a SERVAUTH resource profile for each NSS IPSec client certificate added to the NSS server’s key ring, and give each NSS IPSec client’s user ID access to the profiles created for its own certificates.

The name of such a resource profile is EZB.NSSCERT.sysname.mappedlabelname.HOST, where sysname is the name of the z/OS system running the NSS server and mappedlabelname is the mapped name of the certificate's label in the key ring. For details about determining a certificate label's mapped name, see “NSS server certificate label naming considerations” on page 1063.

This can be accomplished with the following commands:

```
RDEFINE SERVAUTH EZB.NSSCERT.sysname.mappedlabelname.HOST UACC(NONE)
PERMIT EZB.NSSCERT.sysname.mappedlabelname.HOST CLASS(SERVAUTH) ID(userid) ACCESS(READ)
SETROPTS GENERIC(SERVAUTH) REFRESH
SETROPTS RACLIST(SERVAUTH) REFRESH
```

e. Create a SERVAUTH resource profile for each certificate authority (CA) certificate that could be used by an NSS IPSec client, and give the NSS client's user ID access to the profiles.

When the digital signature mode of authentication is used, an NSS IPSec client can provide a remote security endpoint with information about certificate authorities that are trusted by the NSS client. The remote security endpoint should use this information as a hint to decide which of its certificates to use when creating its signature.

By default, an NSS IPSec client sends a remote security endpoint information about all the certificate authorities that the NSS IPSec client is authorized to advertise. This can result in an NSS IPSec client sending a large amount of data to a remote security endpoint. Use the CaLabel parameter on the RemoteSecurityEndpoint statement to reduce the amount of data sent to specific remote security endpoints. For details about the RemoteSecurityEndpoint statement, see z/OS Communications Server: IP Configuration Reference.

A SERVAUTH resource profile is used to authorize NSS IPSec clients to use a CA. A SERVAUTH resource profile must be created for each CA certificate that could be used by an NSS IPSec client. The name of such a resource profile is EZB.NSSCERT.sysname.mappedlabelname.CERTAUTH, where sysname is the name of the z/OS system running the NSS server and mappedlabelname is the mapped name of the certificate's label in the key ring. For details about determining a certificate label's mapped name, see “NSS server certificate label naming considerations” on page 1063. An NSS IPSec client's user ID must be given access to this profile before it can use the corresponding CA certificate.

This can be accomplished with the following commands:

```
RDEFINE SERVAUTH EZB.NSSCERT.sysname.mappedlabelname.CERTAUTH UACC(NONE)
PERMIT EZB.NSSCERT.sysname.mappedlabelname.CERTAUTH CLASS(SERVAUTH) ID(userid) ACCESS(READ)
SETROPTS GENERIC(SERVAUTH) REFRESH
SETROPTS RACLIST(SERVAUTH) REFRESH
```

f. Create a SERVAUTH resource profile for each certificate that an NSS XMLAppliance client could retrieve and give the user ID of the NSS XMLAppliance client access to the appropriate profiles.

In contrast to the IPSec discipline, the XMLAppliance discipline does not distinguish between host, site, or certificate authority certificates. For any given certificate request, the NSS server first checks the EZB.NSSCERT.sysname.mappedlabelname.HOST profile. If that check fails, the server then checks the EZB.NSSCERT.sysname.mappedlabelname.CERTAUTH profile. If the NSS XMLAppliance client has read access to either profile, the server permits access to the certificate resource. It is up to the NSS server administrator to allow or deny access to each certificate, and it is up to the XML appliance administrator to determine how each certificate should be used. The user ID of an NSS XMLAppliance client must be given access to one of these profiles before it can use the corresponding certificate. For examples on how to define the required profiles and permit access, see step “8.d” on page 1061 and step “8.e” on page 1061, under “Steps for authorizing resources for NSS” on page 1058. For details about determining the mapped name of a certificate label, see “NSS server certificate label naming considerations” on page 1063.
g. Create a SERVAUTH resource profile for the private key of each certificate to which an NSS XMLAppliance client requires access and give the user ID of the NSS XMLAppliance client access to the profiles.

Use the SERVAUTH resource profile to authorize NSS XMLAppliance clients to retrieve the private key from a certificate, and to locally perform any RSA operations that are based on the private key or to make ICSF calls requesting RSA operations on System z for ICSF-protected keys. You must create a SERVAUTH resource profile for each private key against which the XMLAppliance client needs to perform operations. The name of such a resource profile is EZB.NSSCERT.sysname.mappedlabelname.PRIVKEY, where sysname is the name of the z/OS system running the NSS server and mappedlabelname is the mapped name of the certificate label in the key ring. Ensure that the user ID of an NSS XMLAppliance client has appropriate access to this profile so that it can retrieve the private key or perform any RSA operations that are based on the private key. This can be accomplished with the following commands:

```
RDEFINE SERVAUTH EZB.NSSCERT.sysname.mappedlabelname.PRIVKEY UACC(NONE)
PERMIT EZB.NSSCERT.sysname.mappedlabelname.PRIVKEY CLASS(SERVAUTH) ID(userid)
ACCESS(READ)
SETROPTS GENERIC(SERVAUTH) REFRESH
SETROPTS RACLIST(SERVAUTH) REFRESH
```

For details about determining the mapped name of a certificate label, see “NSS server certificate label naming considerations” on page 1063.

h. Create the following SERVAUTH profiles to enable users to remotely monitor (IPSEC.DISPLAY) or manage (IPSEC.CONTROL) NSS clients:

- EZB.NETMGMT.sysname.clientname.IPSEC.DISPLAY
- EZB.NETMGMT.sysname.clientname.IPSEC.CONTROL

For more information, see the information about the -z option of the ipsec command in “NSS client authorization example” on page 1064. For more details about managing network security, see z/OS Communications Server: IP System Administrator's Commands. For details about the network management interface, see z/OS Communications Server: IP Programmer's Guide and Reference.

8. If you are using the NSS XMLAppliance private key service with ICSF-protected private keys, authorize the NSS server to the Integrated Cryptographic Service Facility (ICSF).

ICSF is required when using the RSA operations in the XMLAppliance private key service. The XMLAppliance private key service uses ICSF in the following ways:

- Encrypting signature data for the XMLAppliance private key service RSA signature generation message flow.
- Decrypting data for the XMLAppliance private key service RSA decryption message flow.

ICSF provides cryptography support through various cryptographic hardware features. The cryptographic features that are available to your applications depend on your processor or server model. For information about which features are available on your hardware, see the information about callable service support by hardware configuration in z/OS Cryptographic Services ICSF Overview. For details about configuring ICSF, see z/OS Cryptographic Services ICSF Administrator's Guide.

When using a cryptographic coprocessor, the callable ICSF service names that are used by the XMLAppliance certificate service are as follows:

- CSNDDSG
- CSNDPKD

**Requirement:** If you plan to use the RSA operations within the XMLAppliance private key service, the NSS server must be permitted to access the ICSF cryptographic services (CSFSERV). Use the
following commands to define the appropriate profiles in the CSFSERV class, give the NSS server access to the profiles, activate the CSFSERV class, and refresh the RACF profiles in storage:

```
RDEFINE service-name CLASS(CSFSERV) UACC(NONE)
PERMIT service-name CLASS(CSFSERV) ID(server-name) ACCESS(READ)
SETROPTS CLASSACT(CSFSERV)
SETROPTS RACLIST(CSFSERV) REFRESH
```

9. If XMLAppliance clients using the SAF access service are using certificates for access checks, enable RACF certificate name filtering.

The NSS XMLAppliance SAF access service can use RACF certificate name filtering to map an X.500 distinguished name to a RACF ID when performing SAF access checks. The DIGTNMAP class must be active to perform certificate name filtering. Activate the DIGTNMAP class with the following commands:

```
SETOPS CLASSACT(DIGTNMAP)
SETROPTS RACLIST(DIGTNMAP) REFRESH
```

Create a certificate name filter for each mapping of an X.500 distinguished name to a RACF ID using the following commands:

```
RACDCERT ID(userid) MAP SDNFILTER('x500dn')
SETROPTS RACLIST(DIGTNMAP) REFRESH
```

For specific details on enabling RACF certificate name filtering, see z/OS Security Server RACF Security Administrator's Guide.

10. The NSSD uses ICSF callable services for ECDSA digital signature support. The services it uses are the PKCS11 private key sign service and the PKCS11 public key verify service. You can control access to these services with RACF, using the CSFSERV general resource class, and the CSF1PKS and CSF1PKV profiles.

If the CSFSERV class is defined, and the CSF1PKS and CSF1PKV profiles are defined, grant the NSSD user ID read access to the defined profiles using the following commands:

```
PERMIT CSF1PKS CLASS(CSFSERV) ID(NSSD) ACCESS(READ)
PERMIT CSF1PKV CLASS(CSFSERV) ID(NSSD) ACCESS(READ)
SETROPTS RACLIST(CSFSERV) REFRESH
```

See z/OS Cryptographic Services ICSF Administrator's Guide for more information about the CSFSERV general resource.

**NSS server certificate label naming considerations**

During the processing of certificate operations, the NSS server validates that an NSS client is authorized to access the certificates required to complete the operation. The NSS server consults SERVAUTH profiles to perform this validation. The profile names consulted by the NSS server are dynamically constructed by the NSS server using the following information:

- The system name on which the NSS server is running
- The label of the certificate this is used during a certificate operation
- The certificate operation that is being performed:
  - When processing a request to create a signature, the format of the profile that is consulted is EZB.NSSCERT.sysname.mappedlabelname.HOST.
  - When processing a request to obtain a list of CA certificates, the format of the profile consulted is EZB.NSSCERT.sysname.mappedlabelname.CERTAUTH.
  - When processing a request to retrieve a private key that is not protected by Integrated Cryptographic Service Facility (ICSF) or to use an ICSF-protected private key, the format of the profile consulted is EZB.NSSCERT.sysname.mappedlabelname.PRIVKEY.

The NSS server creates a mapped label name using the following algorithm:
• All lowercase alphabetic characters in a certificate's label are changed to uppercase. This is necessary because the class descriptor table for the SERVAUTH profile permits only uppercase profile names.
• The asterisk (*), percent sign (%), and ampersand (&) are replaced by a dollar sign ($). This is necessary because these characters have special meaning when generic profile processing is active.
• All embedded blanks are also replaced by a dollar sign ($). This is necessary because blanks are not allowed in SERVAUTH profile names.

Rules:
• The administrator of the NSS server must define profiles using the mapped label names generated by this algorithm. When the certificate's label name contains lowercase characters, the administrator must change each lowercase character to uppercase. When the certificate's label name contains the characters *, %, & or a blank character, the administrator must replace each occurrence with a dollar sign ($) character.
• When a certificate label contains the period character (.), ensure that the corresponding SERVAUTH profile contains matching qualifiers. For example, if you request a certificate with the label CERTIFICATE.123.ABC for a private key operation, the NSS server checks a SERVAUTH profile named EZB.NSSCERT.sysname.CERTIFICATE.123.ABC.PRIVKEY; defining a SERVAUTH profile named EZB.NSSCERT.sysname.CERTIFICATE.*.PRIVKEY does not permit access to the private key of the certificate.

Using this algorithm, it is possible that multiple certificates can result in the same mapped name. This is shown in Table 55 on page 1064.

<table>
<thead>
<tr>
<th>Label</th>
<th>Mapped label</th>
</tr>
</thead>
<tbody>
<tr>
<td>CERTIFICATE_123</td>
<td>CERTIFICATE_123</td>
</tr>
<tr>
<td>Certificate_123</td>
<td>CERTIFICATE_123</td>
</tr>
<tr>
<td>CERTIFICATE 123</td>
<td>CERTIFICATE$123</td>
</tr>
<tr>
<td>CERTIFICATE%123</td>
<td>CERTIFICATE$123</td>
</tr>
<tr>
<td>CERTIFICATE*123</td>
<td>CERTIFICATE$123</td>
</tr>
<tr>
<td>CERTIFICATE&amp;123</td>
<td>CERTIFICATE$123</td>
</tr>
<tr>
<td>CERTIFICATE$123</td>
<td>CERTIFICATE$123</td>
</tr>
</tbody>
</table>

Tip: When creating certificates for the NSS server's key ring, avoid using lowercase alphabetic characters, blanks, and the characters *, %, and & in the certificate's label.

NSS client authorization example
Consider the configuration shown in Figure 131 on page 1065.
In this example, note the following configuration:

- Stack STACK1 is defined as an NSS IPSec client in the IKE daemon configuration file on system SYSTEMA. The client name for STACK1 is SYSTEMA_STACK1. The user ID associated with SYSTEMA_STACK1 is A1S1. The user ID A1S1 must be defined to the external security manager on system SYSTEMB.

- Client SYSTEMA_STACK1 is configured to use the NSS certificate service. On system SYSTEMB, the user ID A1S1 must be given read access to the following SERVAUTH profile:

  EZB.NSS.SYSTEMB.SYSTEMA_STACK1.IPSEC.CERT

- Client SYSTEMA_STACK1 is configured to use the NSS remote management service. On system SYSTEMB, the user ID A1S1 must be given read access to the following SERVAUTH profile:

  EZB.NSS.SYSTEMB.SYSTEMA_STACK1.IPSEC.NETMGMT

- The NSS server on system SYSTEMB is configured to use the key ring EnterpriseRing. This key ring is owned by the NSSD user ID. Certificates for all NSS IPSec clients are stored on this key ring.

  The NSS server’s AT-TLS policy must also specify a key ring from which to obtain the NSS server’s personal certificate for use during the TLS negotiation with an NSS client. The NSS server’s AT-TLS policy can specify the same key ring as the NSS server’s configuration file, or it can specify a different key ring. In either case, the AT-TLS policy should specify which personal certificate to use to represent the NSS server by using the CertificateLabel parameter on the TTLSConnectionAdvancedParms statement. If this parameter is not configured, AT-TLS attempts to use the default certificate, if one exists, on the configured key ring. If no default certificate exists on the configured key ring and the CertificateLabel parameter is not configured, the TLS negotiation between the NSS client and the NSS server will fail.
The IKE daemon's AT-TLS policy also specifies a key ring. This key ring is used to locate the certificate that was used to sign the NSS server's personal certificate. If the IKE daemon's AT-TLS key ring does not contain this signing certificate, TLS negotiation will fail to verify the NSS server's certificate and the TLS negotiation between the NSS client and the NSS server will fail.

In this example, there is one Personal certificate stored on the key ring for client SYSTEMA_STACK1. On system SYSEYMB, the user ID A1S1 must be given read access to the following SERVAUTH profile before the NSS server can use this certificate to create a signature for client SYSTEMA_STACK1:

```
EZB.NSSCERT.SYSTEMB.A1S1_CERT.HOST
```

In this example, there is also one CertAuth certificate stored on the key ring that should be advertised to IPSec peers by client SYSTEMA_STACK1. On system SYSEYMB, the user ID A1S1 must be given read access to the following SERVAUTH profile before the NSS server can inform client SYSTEMA_STACK1 that it can advertise this CERTAUTH certificate to its peers:

```
EZB.NSSCERT.SYSTEMB.CA.CERTAUTH
```

• The user LARRY will issue the `ipsec` command with the `-z` option to monitor and manage client SYSTEMA_STACK1. On system SYSTEMB, the user ID LARRY must be given read access to the following SERVAUTH profiles:

```
EZB.NETMGMT.SYSTEMB.SYSTEMA_STACK1.IPSEC.DISPLAY
EZB.NETMGMT.SYSTEMB.SYSTEMA_STACK1.IPSEC.CONTROL
```

The user LARRY will also issue the `ipsec` command with the `-x` option to display information about the NSS server. On system SYSTEMB, the user ID LARRY must be given read access to the following SERVAUTH profile:

```
EZB.NETMGMT.SYSTEMB.SYSTEMB.NSS.DISPLAY
```

In addition, the user LARRY will issue the `ipsec` command with the `-w` option to display information from the IKE daemon about NSS IPSec clients. On system SYSTEMA, the user ID LARRY must be given read access to the following SERVAUTH profile:

```
EZB.NETMGMT.SYSTEMA.SYSTEMA.IKED.DISPLAY
```

**Tip:** A wildcard can be used in the profiles to reduce the number of profile entries that must be defined.

**NSS server configuration considerations**

This topic describes configuration issues specific to the NSS server.

**Run-time environment**

The NSS server is a z/OS UNIX application; it requires the z/OS UNIX file system. The NSS server can be started from an MVS started procedure, from the z/OS shell, with the AUTOLOG statement in the TCP/IP profile, or by using the COMMANDxx member of PARMLIB. The NSS server must be started by a RACF-authorized user ID, and it must be in an APF-authorized library. For more information about how to start the NSS server, see "Starting the NSS server" on page 1074.

The NSS server uses the MVS operator's console, syslogd, CTRACE, and STDOUT for its logging and tracing. The MVS operator's console and STDOUT are used for major events such as initialization, termination, and error conditions. Syslogd is used for logging events related to the processing of NSS requests. CTRACE is used for detailed tracing and debugging.

The NSS server uses a standard message catalog. The message catalog must be in the UNIX file system. The directory location for the message catalog path is set by the environment variables NLSPATH and LANG.

The NSS server uses ICSF and System SSL for encryption and key management services to provide certificate services to NSS IPSec clients. If the NSS IPSec clients are configured in FIPS 140 mode, you
must also configure the NSS server in FIPS 140 mode so that it invokes ICSF and System SSL in FIPS 140 mode. This configuration is required for the entire system to be in FIPS 140 mode.

**Language Environment run-time considerations**

When starting the NSS server from a started or cataloged procedure, you should typically start it directly from the SEZALOAD data set using PGM=EZANSSD. However, there is a situation in which you might want to start the NSS server using BPXBATCH.

When the NSS server is started using PGM=EZANSSD, the STDENV DD card, if used, is passed directly to the NSS server program. Language Environment does not get access to the STDENV environment variables. As a result, any Language Environment run-time options set in the STDENV DD data set using the _CEE_RUNOPTS environment variable are ignored. In this case, Language Environment run-time options must be passed on the PARM parameter, and the options must be specified before any NSS server options. However, the PARM parameter allows a maximum of 100 characters. If the Language Environment run-time options plus NSS server parameters that you want exceed 100 characters, consider using BPXBATCH to start the NSS server. When PGM=BPXBATCH is used, the Language Environment variable _CEE_RUNOPTS can be included on the STDENV DD card to specify run-time options in excess of 100 characters long.

**Steps for configuring the NSS server**

The network security services (NSS) server supports the IPSec and XMLAppliance disciplines. IPSec discipline services include the IPSec certificate service and the IPSec remote management service, and XMLAppliance discipline services include the XMLAppliance SAF access service, the XMLAppliance certificate service, and the XMLAppliance private key service.

**Procedure**

Perform the following steps to configure the NSS server:

1. Create the NSS server configuration file.
   - Use the IBM Configuration Assistant for z/OS Communications Server to establish NSS server settings. Establish the settings using the NSS perspective of the IBM Configuration Assistant for z/OS Communications Server, and then use the Install Configuration File button on the Image Information tab to store the generated NSS server configuration file on the z/OS system.
   - Tip: A sample configuration file is provided in /usr/lpp/tcpip/samples/nssd.conf.
   - The following search order is used by the NSS server to locate the configuration data set or file:
     a. If the environment variable NSSD_FILE has been defined, the NSS server uses the value as the name of an MVS data set or z/OS UNIX file to access the configuration data.
     b. /etc/security/nssd.conf
   - You can specify statements in the configuration file using a variety of EBCDIC code pages. Use the NSSD_CODEPAGE environment variable to specify the code page that you want to use. The default code page is IBM-1047.
   - The NSS server configuration file allows the URL of a certificate or certificate bundle that is on an HTTP web server to be associated with the label of a certificate on the key ring of the network security server. See “Using hash and URL certificate encoding types” on page 1071 for additional details.

2. Optionally, set the _BPX_JOBNAME environment variable.
   - When starting the NSS server from the z/OS shell, you should set the environment variable _BPX_JOBNAME. This enables a specific job name to be used when reserving ports for the NSS server. This name can also be used with the STOP or MODIFY console commands. For more information about _BPX_JOBNAME, see z/OS UNIX System Services Planning.

3. Authorize the NSS server to the external security manager, as described in “Steps for authorizing resources for NSS” on page 1058.

4. Configure and start syslogd.
The NSS server uses the local4 facility when writing messages to syslogd. For performance purposes, syslogd should use z/OS File System as its underlying file system. For more information about syslogd, see “Configuring the syslog daemon” on page 199.

5. Optionally, update the NSS server environment variables.

The following environment variables are used by the NSS server and can be tailored to a particular installation.

**NSSD_CODEPAGE**

Use the NSSD_CODEPAGE variable to specify the EBCDIC code page to be used when reading the configuration file. For more information about NSSD environment variables and the supported code pages, see z/OS Communications Server: IP Configuration Reference.

**NSSD_CTRACE_MEMBER**

Used by the NSS server to locate a parmlib member for NSS server CTRACE customization. For more information about the TCP/IP services component trace for the NSS server, see z/OS Communications Server: IP Diagnosis Guide.

**NSSD_FILE**

Used by the NSS server in the search order for the NSS server configuration file. For details about the search order used for locating this configuration file, see step “1” on page 1067.

**NSSD_PIDFILE**

Used by the NSS server in the search order for the NSS server PID file. The search order for the NSS server PID file is as follows:

a. NSSD_PIDFILE environment variable
b. /etc/nssd.pid

6. Set up the NSS server key ring.

The NSS server's key ring serves a similar purpose as the IKE daemon's key ring. It contains certificates that are used in the process of creating and verifying signatures that are exchanged during digital signature authentication. A personal certificate or site certificate contained on the key ring of the NSS server represents the identity of an NSS IPSec client, whereas a certificate contained on the IKE daemon's key ring represents a local stack's identity. Certificates for all NSS IPSec clients must be on this one key ring.

If a personal certificate or site certificate that is contained on the key ring of the NSS server is signed by a certificate authority, then the certificate of that certificate authority must also be connected to the key ring of the NSS server. If the certificate authority is a subordinate certificate authority (such as one that was created by another certificate authority) you should ensure that all the certificate authority certificates that make up the trust chain are connected to the key ring of the NSS server.

The same commands that are used to create and manage the IKE daemon's key ring also apply to the NSS server's key ring. For examples of how to create and manage the IKE daemon's key ring, see Appendix E, “Steps for preparing to run IP security,” on page 1331.

You must create a SERVAUTH resource profile for each NSS IPSec client certificate that is added to the key ring of the NSS server. For details, see step “8.d” on page 1061.

7. Update the TCP/IP profile and policy files.

You should update the TCP/IP profile to reserve the port on which the NSS server will listen. If IP security is enabled, consider updating the default IP filter rules in the TCP/IP profile to enable the NSS server to communicate with NSS clients. The IP security policy defined in Policy Agent configuration files must be updated to enable the NSS server to communicate with NSS clients. AT-TLS should be enabled and rules should be defined to protect NSS server communication with NSS clients.

For additional details concerning these tasks, see “TCP/IP stack considerations” on page 1069.

8. Update the NSS server cataloged procedure (if starting as a started procedure).

If the NSS server is to be started by a procedure, create the cataloged procedure by copying the sample in SEZAINST(NSSD) to your system. Specify NSS server parameters and change the data set names to suit your local configuration. For a copy of the sample, see z/OS Communications Server: IP Configuration Reference.
Results

If these steps are completed successfully, you should be able to start the NSS server. For details, see “Starting the NSS server” on page 1074.

TCP/IP stack considerations

This topic describes TCP/IP stack considerations, including port reservation, IP filtering, and AT-TLS policy.

Port reservation

By default the NSS server uses TCP port 4159, but this value is configurable using the Port parameter of the NssConfig statement in the NSS server configuration file. For additional details about the NssConfig statement, see z/OS Communications Server: IP Configuration Reference.

Tip: Update the PORT statement in the TCP/IP profile to reserve the port that the NSS server will use when listening for client connections.

| PORT 4159 TCP NSSD |

IP filtering

The NSS server communicates with NSS clients using the TCP protocol. The NSS server binds to all stacks using either INADDR_ANY or in6addr_any as the IP address. IP filters rules must be defined for any IP security stacks that contain an interface to which the NSS client will connect (for details about configuring the IKE daemon as an NSS client, see Chapter 17, “IP security,” on page 855). Remote IPSec clients use an ephemeral port when connecting to the NSS server. Ephemeral ports are generally in the range 1024–65355.

Two types of IP filter policy can be defined for a z/OS stack:

- You can define a default IP filter policy in the TCP/IP profile. Updating default IP filter policy to permit communications between the NSS server and NSS clients is optional. Default IP filter policy is in effect only when IP security filter policy cannot be loaded or when the `ipsec -f default` command has been issued.

For details about defining default IP filter policy in the TCP/IP profile, see z/OS Communications Server: IP Configuration Reference.

The following default policy contains IPSECRule definitions that allow IPv4 and IPv6 NSS server traffic with NSS clients:

```
IPSEC LOGENable
; Rule      SrcAddr DstAddr   Logging Protocol   SrcPort    DestPort     Routing Secclass
; OSPF protocol used by Omproute
IPSECRule *  *       NOLOG   PROTO OSPF
; IGMP protocol used by Omproute
IPSECRule *  *       NOLOG   PROTO 2

IPSECRule *  *       LOG     TCP        SRCPort 4159 DESTport *
; Network security services (NSS) server access to the NSS client
IPSEC6Rule *  *       LOG     TCP        SRCPort 4159 DESTport *
ENDIPSEC
```

Rule: The SRCport value in the filter rules must include the value specified on the port parameter of the NssConfig statement in the NSS server configuration file.
• You can define an IP security filter policy in Policy Agent configuration files. IP security filter policy must be updated to permit communications between the NSS server and NSS clients.

For details about defining IP security policy files, see the Policy Agent and policy applications topic in z/OS Communications Server: IP Configuration Reference.

An example of an IpFilterRule statement for IPv4, an IpFilterRule statement for IPv6, and an IpGenericFilterAction statement that allows NSS clients to communicate with the NSS server is as follows:

```c
IpFilterRule NssTrafficIPv4
{
    IpSourceAddr all4
    IpDestAddrSet all4
    IpService
    {
        SourcePortRange 4159
        DestinationPortRange 1024 65535
        Protocol tcp
        Direction bidirectional InboundConnect
        Routing local
    }
    IpGenericFilterActionRef permit-nolog
}
IpFilterRule NssTrafficIPv6
{
    IpSourceAddr all6
    IpDestAddrSet all6
    IpService
    {
        SourcePortRange 4159
        DestinationPortRange 1024 65535
        Protocol tcp
        Direction bidirectional InboundConnect
        Routing local
    }
    IpGenericFilterActionRef permit-nolog
}
IpGenericFilterAction permit-nolog
{
    IpFilterAction permit
    IpFilterLogging no
}
```

**Rule:** The DestinationPortRange value on the IpService statements must include the value specified on the port parameter of the NssConfig statement in the NSS server configuration file.

**AT-TLS policy**

Communications between the NSS server and NSS clients must be secured using Application Transparent Transport Layer Security (AT-TLS). You must define AT-TLS rules to secure this communication. Enable AT-TLS processing for a stack by specifying the TTLS parameter on the TCPCONFIG statement in the TCP/IP profile. Specific AT-TLS policy is configured in Policy Agent configuration files. For details about enabling AT-TLS and configuring AT-TLS policy, see Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1093.

**Tip:** Define AT-TLS policy such that only cipher suites requiring TLS encryption are exchanged with NSS clients. Failure to restrict the cipher suites to those requiring encryption can result in sensitive information flowing in the clear across an untrusted network.

**Rule:** You must define AT-TLS policy for each stack through which the NSS server will communicate with an NSS client.

**Requirement:** The NSS server acts as the server during an SSL handshake. To act in the server role of an SSL handshake, the NSS server must have access to a private key and certificate verifying its ownership of that private key. For information about creating and managing keys and certificates for servers using AT-TLS, see Appendix B, “TLS/SSL security,” on page 1299.

A sample AT-TLS policy is located in `/usr/lpp/tcpip/samples/pagent_TTLS.conf`. 
**Rule:** The LocalPortRange value on the TTLSRule statement must include the value specified on the port parameter of the NssConfig statement in the NSS server configuration file.

### Using hash and URL certificate encoding types

During an IKE flow, security endpoints can authenticate each other by exchanging certificate information in certificate payloads and by performing digital signature operations on that certificate information. When the IKED negotiates an IKEv2 phase 1 Security Association on behalf of a network security client, the IKED uses the network security server for these digital signature operations. Encoded certificate information that is received from a remote security endpoint is forwarded to the network security server. Encoded certificate information that is sent to a remote security endpoint by the IKED is obtained from the network security server.

There are several encoding types defined for use in IKEv1, but the only encoding type that must be supported by an IKEv1 implementation is an X.509 certificate signature. Two additional certificate encoding types must be supported by an IKEv2 implementation:

- Hash and URL of an X.509 certificate
- Hash and URL of an X.509 bundle

Generally a hash and URL of a certificate or certificate bundle is considerably smaller than the certificate or the bundle that it represents. Less data is exchanged between IKE peers and between the IKED and the network security server. Although smaller message sizes might improve the efficiency of network resources, using hash and URL encoding requires more processing. The NSSD must communicate with an HTTP server to retrieve the certificate using the URL, and it must validate the certificate using the hash. This communication, when needed, increases the amount of time it takes to complete an IKEv2 phase 1 negotiation.

If you want the NSSD to create hash and URL certificates to send to peers, you must create files on an HTTP server that contain the certificates and the certificate bundles. You must also include the URLs of those files in the NSSD configuration file. See “Enabling the NSSD to generate hash and URL certificate encoding” on page 1071.

**Rule:** Even if you put a certificate or a certificate bundle on an HTTP server and add the URLs to the NSSD configuration file, you still need to store that certificate on the key ring of the NSSD.

The NSSD can accept hash and URL encoded certificates that it receives from its peers. In that case, the NSSD uses the URLs sent by the peers to locate the certificates. The NSSD caches data that it retrieves from an HTTP server using a URL. See “Enabling the NSSD to process received hash and URL certificate encoding” on page 1072.

Even when URL information is configured for the NSSD, it is ultimately the responsibility of the network security client to decide whether the network security server should use hash and URL encoding. See “Controlling the use of hash and URL certificate encoding” on page 1072.

### Enabling the NSSD to generate hash and URL certificate encoding

To enable the NSSD to generate hash and URL certificate encoding, perform the following steps:

1. Export the certificates in CERTDER format from RACF.

   Use the RACDCERT EXPORT command with the CERTDER format option to create a data set that contains the binary DER encoding of a certificate on a key ring. If the HTTP server is running on the local system, copy the data set to the location specified by the CertificateURL parameter value. If the HTTP server is running on a remote system, transfer the data set to the appropriate location using a utility such as FTP. For more details about the RACDCERT command, see z/OS Security Server RACF Command Language Reference.

   **Tip:** Do not export the private key when you export the certificate from RACF.

2. Populate the HTTP server with exported certificates.

3. Identify the resources to the NSSD using the CertificateURL parameter.
The CertificateURL parameter in the configuration file of the NSS server associates a certificate on the key ring of the NSS server with a URL that identifies an HTTP server and a file on that server that contains the binary DER encoding of the certificate. For more details about the CertificateURL parameter, see z/OS Communications Server: IP Configuration Reference.

4. Create the certificate bundles that you need by issuing the `certbundle` command.

Use the `certbundle` command to create a file or data set that contains a certificate bundle. If the HTTP server is running on the local system, copy the file or data set to the location specified by the CertificateBundleURL parameter value. If the HTTP server is running on a remote system, transfer the file or data set to the appropriate location using a utility such as FTP. For more details about the `certbundle` command, see z/OS Communications Server: IP System Administrator's Commands. For more details about creating certificate bundles, see “Creating certificate bundles” on page 1072.

5. Populate the HTTP server with the certificate bundle files.

6. Identify the resources to the NSSD using the CertificateBundleURL parameter.

The CertificateBundleURL parameter in the configuration file of the network security server associates a certificate on the key ring of the network security server with a URL that identifies an HTTP server and a file on that server that contains the certificate in a certificate bundle. For more details about the CertificateBundleURL parameter, see z/OS Communications Server: IP Configuration Reference.

### Enabling the NSSD to process received hash and URL certificate encoding

To enable the NSSD to process received hash and URL certificate encoding, perform the following steps:

1. Ensure that HTTP traffic is not impeded by IP filter rules.

   **Tip:** If IP filtering is enabled on the system where the network security server is running, ensure that the correct filter rules are in place to allow communication with the HTTP servers that are identified on a CertificateURL or CertificateBundleURL, as well as any HTTP servers used by the remote security endpoint of the network security client. This communication typically uses the TCP protocol with an ephemeral source port and a destination port of 80.

2. Use the URLCacheInterval parameter on the IPSecDisciplineConfig statement in the NSSD configuration file to determine the maximum amount of time that URL data is cached before being re-fetched from an HTTP server. For more details about the URLCacheInterval parameter, see z/OS Communications Server: IP Configuration Reference.

### Controlling the use of hash and URL certificate encoding

To control the use of hash and URL certificate encoding, configure IP security policies to accept hash and URL encoded certificates by setting the CertificateURLLookupPreference parameter on the KeyExchangePolicy and KeyExchangeAction statements in the IP security policy configuration file of network security clients. For more details about the CertificateURLLookupPreference parameter on the KeyExchangePolicy and KeyExchangeAction statements, see z/OS Communications Server: IP Configuration Reference.

### Creating certificate bundles

Certificate bundles are used to store a group of related certificate information. A certificate bundle contains zero or more certificates and zero or more certificate revocation lists (CRLs). When an IKEv2 negotiation uses a digital signature authentication method, this certificate information can be exchanged using a certificate bundle. When information is exchanged using a certificate bundle, a URL that identifies the certificate bundle and a hash of the data in the certificate bundle is sent to the remote security endpoint. The remote security endpoint then retrieves the certificate bundle from an HTTP server, and uses the bundle when it validates the digital signature.

A certificate bundle can hold in a single location all relevant information about an entire trust chain. The following types of information can be included in a certificate bundle:

- The certificate that was used to create a digital signature
- The certificates of certificate authorities in the trust chain
• Certificate revocation lists (CRLs)

Although consolidating this information in one place has advantages, consolidation might cause the remote security endpoint to retrieve unneeded information. Often the remote security endpoint already has knowledge of most of the certificates in the trust chain and is capable of retrieving CRL information using another method. In such cases, it might be more efficient to use individual certificates, rather than a certificate bundle.

You can use the `certbundle` command to create one or more files, each of which contains one certificate bundle. A certificate bundle options file is required as input to the `certbundle` command. The certificate bundle options file identifies how many certificate bundles are created, as well as the contents of each certificate bundle.

**Guidelines:**

• All certificate information in a certificate bundle file should be for the same trust chain.
• You should not include CRL information in a certificate bundle except when there is no other way for the remote security endpoint to retrieve the CRL information. Because certificate authorities periodically issue new CRLs, CRL information that is stored in a certificate bundle must be constantly updated to contain the most recent CRL information.

**Rule:** Do not put the certificate for the root certificate authority in a certificate bundle. An IKE implementation cannot accept a certificate for the root certificate authority from an untrusted source and, because certificate bundles are considered an untrusted source, any root certificates they contain are unusable. In addition, putting this certificate in the certificate bundle needlessly increases the size of the certificate bundle.

**Steps for creating certificate bundles**

You can use certificate bundles to consolidate all relevant information about an entire trust chain. The types of information that can be included in a certificate bundle are the certificate that was used to create a digital signature, the certificates of certificate authorities in the trust chain, and certificate revocation lists (CRLs).

**Before you begin**

Obtain from the certificate authority any certificate revocation lists (CRLs) that you want to put in a certificate bundle.

**Procedure**

Perform the following steps to create certificate bundles:

1. Store the CRLs that you are going to include in a certificate bundle in a file or data set.
2. Create a certificate bundle options file. See The z/OS UNIX certbundle command options file in z/OS Communications Server: IP System Administrator's Commands for more information.
3. For each certificate bundle that you are creating, define a CertBundleOptions statement:
   a) Use the KeyRing parameter to identify the key ring containing any certificates that you want to include.
   b) Use the CertificateChain parameter to specify the label of the certificate that is lowest in any complete trust chain that you want to include (excluding the root CA). The CertificateChain parameter generates a certificate bundle file that contains an optimal set of certificates.
   c) Use the CertificateLabel parameter to specify the label of any individual certificates that you want to include. Use the CertificateLabel parameter only when you need to include fewer certificates than the entire chain.
   d) Use the CRLFile parameter to identify the files that contain any CRLs that you want to include.
   e) Use the BundleFile parameter to identify the name of the certificate bundle file that you are creating.
4. Provide read access to the key rings that are specified in the certificate bundle options file to the user ID under which the **certbundle** command is issued. See *z/OS Security Server RACF Command Language Reference* for details concerning access to key rings.

5. Issue the **certbundle** command, specifying the certificate bundle options file that you just created.

**Controlling the NSS server**

This topic describes starting and stopping the NSS server, modifying the configuration file, and displaying configuration file parameters.

**Starting the NSS server**

The NSS server can be started in the following ways:

- Using an MVS procedure from the MVS operator console. A sample start procedure is provided in `SEZAINST(NSSD)`.
- From the z/OS shell, by starting OMVS and then issuing the **nssd** command.
- Using the COMMDNxx member of PARMLIB. This allows the NSS server to be automatically started when the system is IPLed. For information about the use and configuration of the COMMDNxx member of PARMLIB, see *z/OS MVS Initialization and Tuning Reference*.
- Using the AUTOLOG statement in the TCP/IP profile.

**Tips:**

- You should not start the NSS server using the AUTOLOG statement in a stack's profile. If the NSS server is listed in a stack's AUTOLOG statement, the server is cancelled if it is already running when that stack starts. This results in the NSS server losing any cached information that it has in place for NSS clients previously connected through all stacks, and could increase the overall recovery time when a TCP/IP stack recycles.
- If you start the NSS server from the z/OS shell and you stop the shell environment from scrolling, then when the **nssd** command needs to display data to the shell, the NSS server might stop and wait indefinitely for the shell to scroll and make output buffer space available for the data.
- When running from an MVS procedure, set the environment variables using the STDENV DD statement in the NSS server procedure.

**Restriction:** Only one instance of the NSS server can run on a z/OS image. If you attempt to start a second instance, the NSS server will fail.

**Stopping the NSS server**

Stop the NSS server from MVS by issuing the following command:

```
STOP procname
```

If the NSS server was started from a cataloged procedure, the `procname` value is the member name of that procedure. If the NSS server was started from the z/OS shell and the environment variable `_BPXJOBNAME` was set, the `procname` value is the same as the `_BPXJOBNAME` value. If the NSS server was started from the z/OS shell and `_BPXJOBNAME` was not set, the `procname` value is based on the `userid`. If the `userid` is 8 characters long, the `procname` is the `userid`. If the `userid` is less than 8 characters long, the `procname` is `useridX`, where `X` is the sequence number that is set by the system. To determine the sequence number, from the **ISPF LOG** window on TSO, issue the following command:

```
/d omvs,u=userid
```

This command displays the programs running under the specified user ID. For more information about `_BPXJOBNAME`, see *z/OS UNIX System Services Planning*.

To stop the NSS server from the z/OS shell, issue the **kill** command (from a superuser ID) to the process ID (PID) that is associated with the NSS server. By default, the NSS server PID is recorded in `/etc/nssd.pid`. You can change the default location using the NSSD_PIDFILE environment variable.
Using the NSS server MODIFY command

The NSS server provides a modify command to take the following actions:

- Reread the configuration file.
  
  Use the MODIFY procname,REFRESH command to flush all cached URLs and reread the NSS server configuration file. Not all NSS server configuration parameters can be updated using this command. For information about which parameters can be dynamically changed, see the parameter descriptions for the NssConfig and IPSecDisciplineConfig statements in z/OS Communications Server: IP Configuration Reference.

- Display the configuration file parameters.
  
  Use the MODIFY procname,DISPLAY command to display configuration values currently in use by the NSS server.

- Display the contents of the URL cache.
  
  Use the MODIFY procname,DISPLAY,URLCACHE command to display the current contents of the URL data cache maintained by the NSS server.

For more information on the MODIFY command, see z/OS Communications Server: IP System Administrator’s Commands.

NSS server failover considerations

NSS IPSec clients can use the NSS certificate service when negotiating phase 1 Security Associations. Network monitoring applications can use the NSS remote management service to display information about NSS IPSec clients. The NSS server should be treated as an application that requires high availability, an application that is able to recover quickly from an outage that impacts the ability of the NSS server to respond to IPSec clients.

Recovery configurations for the NSS server include:

- For recovery of NSS server workload by another NSS server within a sysplex, configure NSS IPSec clients to connect to the NSS server on a non-distributed dynamic VIPA. TCP/IP stacks configured as backup for the dynamic VIPA must have the necessary external security manager definitions and certificates to support the NSS IPSec clients, and an NSS server must be running on the z/OS system hosting the TCP/IP stack configured as backup.

  **Guideline:** Do not configure NSS IPSec clients to connect to a distributed DVIPA address on the NSS server. If a distributed DVIPA is used, the ipsec command and IPSec NMI can manage only NSS IPSec clients that have been distributed to the system on which the ipsec command is being run or to the system on which the IPSec NMI is invoked.

- Alternatively, you can configure an IKE daemon running as an NSS IPSec client to connect to a backup NSS server with the NetworkSecurityServerBackup parameter on the IkeConfig statement in the IKE daemon configuration file. When the IKE daemon is unable to connect to the primary NSS server, or when it loses its connection with the primary server, the IKE daemon attempts to connect to the server configured as backup. This recovery configuration can be used regardless of sysplex configurations. The backup server must be configured with all necessary external security manager definitions and certificates to support the NSS IPSec clients. For additional details about the IkeConfig statement, see z/OS Communications Server: IP Configuration Reference.

NSS server capacity considerations

A single NSS server instance can support a maximum of 500 concurrent NSS client connections, in addition to 10 concurrent NMI client connections.

NSS server certificate revocation support

The NSS server supports the checking of certificate revocation lists (CRLs) when verifying a signature. The NSS server obtains the CRL of a certificate from an HTTP repository, determining the location of the CRL using the CRLDistributionPoints extension of the certificate. The NSS server searches each distribution
point entry in the CRLDistributionPoints extension that contains a reason field pertaining to the all-reasons special value and that references the CRL by using an HTTP URL scheme. The search continues until a CRL that matches the certificate attributes is retrieved or until all distribution points containing an HTTP URL scheme are processed. If a certificate does not contain a CRLDistributionPoints extension or the CRLDistributionPoints extension does not contain at least one suitable distribution point that contains an HTTP URL scheme, then the NSS server is unable to retrieve the CRL.

The NSS server also supports the retrieval of certificate bundles, which can also contain a CRL. If a CRL cannot be retrieved using the CRLDistributionPoints extension of a certificate, the NSS server looks for a CRL in any certificate bundle that has hash and URL information provided by the network security client. The network security client obtains certificate bundle hash and URL information from certificate payloads sent by a remote security endpoint.

Managing network security services

Use the `ipsec` command to display information about NSS IPSec clients that are connected to the NSS server. You can also use this command to manage NSS IPSec clients that are enabled to use the NSS IPSec remote management service and that are currently connected to the NSS server.

Use the `-x` primary option on the `ipsec` command to display connection information about NSS IPSec clients connected to the NSS server.

```
ipsec -x display

Use the -z option on the `ipsec` command to specify the name of an NSS client rather than a name of a local TCP/IP stack. When the -z option is specified, the `ipsec` command obtains information about the NSS client from the NSS server. The -z option is valid only on the system that is running the NSS server. The NSS client that is identified by the -z option must be connected to the NSS server. The NSS client must also be enabled to use the NSS remote management service. The following example uses the -z option to display phase 2 Security Association information about the NSS client client4, where the name client4 was obtained from the previous `ipsec -x display` command.

```
ipsec -y display -z client4
```

```

Chapter 19. Defensive filtering

An external security information and event manager, by analyzing and correlating messages from multiple sources and systems in the network, can take action to block attacks by installing defensive filters in your TCP/IP stack. A defensive filter is an IP filter rule to discard packets, separate from IP security filters, and is typically installed for a short duration (for example, 30 minutes) to block a specific attack or a pattern of attacks. If traffic being blocked by a defensive filter should be blocked on a long-term basis, update your configured IP security policy to add an IP security deny rule.

A defensive filter uses a combination of the following characteristics to target traffic to be discarded:

- IP source or destination address
- IP protocol
- Source or destination port
- ICMP type or code
- Direction of flow
- Type of traffic: Routed or local

For example, a defensive filter might be installed to block all TCP traffic from IP address 10.1.1.1 that is destined for the Telnet server. The characteristics of this filter are the following characteristics:

- IP source address is 10.1.1.1.
- IP protocol is TCP.
- Destination port is 23.
- Direction of flow is inbound.
- Traffic is local.

Defensive filters are given higher priority than IP security filters. That is, IP filter processing first checks any installed defensive filters for a match against a packet, before checking the IP security filters. When a defensive filter is added to a TCP/IP stack, it is placed at the top of the filter search order.

Figure 132 on page 1080 provides an overview of defensive filtering.
Defensive filters are added and managed using the z/OS UNIX `ipsec` command with the -F primary option.

- Defensive filters are typically added as an automated action resulting from an external security information and event manager's analysis. The manager issues the set of `ipsec` commands that install the required defensive filters.
- You can also add a defensive filter by manually issuing the `ipsec` command.
- After a defensive filter is created, you can use the `ipsec` command to update some attributes of the filter, such as its lifetime, and also to display and delete defensive filters.

For more information about the `ipsec` command, see z/OS Communications Server: IP System Administrator's Commands.

**Requirements:**

- You must enable the IP security function for defensive filters to be installed in a stack. If you do not have the IP security function enabled, see “Enabling the IP security function” on page 1087.
- The Defense Manager daemon (DMD) plays an integral role in managing defensive filters, and must be active for defensive filters to be added, updated, or deleted. One instance of the DMD manages all eligible stacks on a z/OS image. An eligible stack is one that is enabled for IP security and that is included in the DMD configuration file with a mode of Active or Simulate. For information about configuring the DMD, see “Steps for configuring the DMD” on page 1088. You can refresh most of the DMD configuration parameters so that options can be changed without recycling the DMD.

**Guideline:** The DMD can support a maximum of 10 concurrent `ipsec` command connections.

**Restriction:** Remote management of defensive filters using a network security services (NSS) server is not supported. Management of defensive filters is provided only through the local `ipsec` command.

---

**Global and stack-specific defensive filters**

A defensive filter has either a global or stack-specific scope.
• A global defensive filter, identified by the -G option on the `ipsec` command, is installed in all eligible stacks on the z/OS image.

• A stack-specific defensive filter is installed in the stack specified by the -p `stackname` option on the `ipsec` command, if the stack is eligible.

When a defensive filter is created, the DMD installs the defensive filter in the eligible stacks and maintains a copy of the filter. The DMD maintains a persistent record of all active defensive filters, global and stack-specific, and the stacks into which those filters are installed.

This persistence enables the DMD to maintain the correct set of installed defensive filters across startup and shutdown activities for TCP/IP stacks, as well as across startup and shutdown of the DMD itself. If the DMD is already running when an eligible TCP/IP stack starts, the DMD installs all applicable defensive filters, global and stack-specific, to that stack. If, when the DMD starts up, it detects that eligible stacks are already running, it ensures that they have or receive the correct set of defensive filters.

After a global defensive filter is created and installed in one or more stacks, you can update it as a global filter, resulting in all copies of the filter being updated. You can also update it in an individual TCP/IP stack, resulting in only that stack's copy of the filter being updated. Similarly, you can delete a global defensive filter globally or only from an individual TCP/IP stack.

### Defensive filter names

A defensive filter receives its name from the `-N `DefensiveFilterName` option when the filter is created. All copies of a global defensive filter have the same name. Global filters and stack-specific filters share the same filter namespace, so a filter name cannot be used for both a global filter and a stack-specific filter. The creation of a stack-specific filter fails if the filter name conflicts with a global filter of the same name, or if there is already a stack-specific filter of the same name in the target stack. The creation of a global filter fails if the filter name conflicts with a global filter of the same name, or if there is already a stack-specific filter of the same name in any stack. This check includes filter names that are in the DMD's persistent memory, even if the corresponding stack is not active.

**Tip:** If you are manually creating defensive filters, avoid conflicts between global and stack-specific filter names by choosing a distinct naming convention for each, such as starting all global filter names with a G.

### Defensive filter modes

Each defensive filter has a mode setting of block or simulate. The defensive filter's mode is set when the filter is created or updated by the `ipsec` command.

By default, defensive filters are in block mode, causing traffic to be discarded. A defensive filter in simulate mode simulates a block and lets you monitor the impact of enabling defensive filters without discarding traffic.

When a packet matches a defensive filter and the mode is simulate, a message is logged indicating that the packet would have been discarded, but the packet is not discarded and IP filtering continues. The packet can subsequently match a defensive filter that is in block mode and be discarded, but the packet will not match another simulation filter.

The DMD configuration file also provides the mode settings Active, Simulate, or Inactive on the `DmStackConfig` statement.

- **Active** enables defensive filtering and honors the mode setting of the individual filters.
- **Simulate** enables defensive filtering and overrides the mode setting of the individual filters; simulate mode is used for all defensive filters installed in the stack.
- **Inactive** disables defensive filtering.

Table 56 on page 1082 summarizes the interaction between the mode setting on the `DmStackConfig` statement and the mode setting in individual filters set by the `ipsec` command.
Table 56. Interaction between the mode setting on the DmStackConfig statement and the mode setting in individual filters

<table>

<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>No defensive filters</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Tips:

- You might want to specify Mode Simulate on the DmStackConfig statement when you are first implementing defensive filtering. All defensive filters in the TCP/IP stack will be treated as if the mode was simulate. When a packet matches a defensive filter, syslog message EZD1722I is generated and IP filtering continues. Defensive filters added to this stack retain the mode setting with which they were added, block or simulate. In most cases, you should use the default mode, block, on the individual filter.

- After completing defensive filter testing in simulate mode, specify Mode Active on the DmStackConfig statement. If there are defensive filters installed in the stack when the mode is changed from simulate to active, the mode on the individual defensive filters is used.

- If defensive filtering is active (DmStackConfig statement with Mode Active) and you want to implement and test additional automation, you can revert to an overall mode of simulate for the whole stack. However, you might want only defensive filters added by the new automation to have a mode of simulate. The automation action can add individual defensive filters with a mode of simulate using the mode keyword on the ipsec -F add command. After testing, you can update the automation action to add defensive filters with a mode of block using the mode keyword on the ipsec -F add command.

For more information about the DmStackConfig statement, see z/OS Communications Server: IP Configuration Reference. For more information about adding or updating a defensive filter with the -F option of the ipsec command, see z/OS Communications Server: IP System Administrator’s Commands.

Allowing administrative access

Defensive filters are checked before IP security filters. To ensure that an administrator is not blocked by a defensive filter, you can exclude the administrator's IP address from defensive filter processing by specifying the administrator's address on the Exclude parameter of the DmStackConfig statement in the DMD configuration file. For more information about the DmStackConfig statement and its parameters, see z/OS Communications Server: IP Configuration Reference.

Filter-match logging

When a packet matches a defensive filter during IP filter processing, a message can be logged indicating that the packet was discarded based on this filter. When a defensive filter is added, filter-match logging can be enabled or disabled for the filter; it is enabled by default. The filter-match logging setting can be updated with the ipsec command for an existing defensive filter.

When a defensive filter is simulating a block, filter match logging is always performed to indicate that a packet would have been discarded based on the defensive filter.

You can limit the number of filter-match messages generated for a defensive filter by specifying a log limit for the defensive filter in one of the following ways:

- Use the loglimit keyword on the ipsec command when you add a defensive filter.
- Use the loglimit keyword on the ipsec command to update a defensive filter.
• Set a default value for one or more TCP/IP stacks using the DefaultLogLimit parameter on the DmStackConfig statement in the DMD configuration file. The DefaultLogLimit value is used when a filter is added without specifying a loglimit value. For more information about the DmStackConfig statement and its parameters, see z/OS Communications Server: IP Configuration Reference.

The log limit limits the average rate of filter-match messages generated in a 5-minute interval for a defensive filter. For example, a loglimit value of 100 limits the average rate of filter-match messages to 100 messages per 5-minute interval. A burst of up to 100 messages is allowed while maintaining the long-term average of 100 messages per 5-minute interval.

A count is kept of suppressed messages. At the end of the 5-minute interval, if there are suppressed filter-match messages, EZD0837I or EZD0838I is generated to report the number of suppressed messages.

TRMD

The Traffic Regulation Manager daemon (TRMD) is responsible for logging defensive filter events that are detected by the stack. These events include filter-match logging and the creation, deletion, and updating of defensive filters.

TRMD and syslogd provide the logging service for defensive filtering. In a Common INET environment, you must configure one instance of TRMD for each stack on a z/OS system. For information about configuring TRMD, see “TRMD” on page 851.

Disabling defensive filters for a single stack

To disable defensive filtering for a TCP/IP stack, while you continue to support defensive filtering for other stacks on the system, take the following actions:

1. Update the DMD configuration file and change the mode of the stack to Inactive on the DmStackConfig statement.
2. Issue the MODIFY REFRESH command for the DMD.

Results:
• All defensive filters are removed from the stack.
• The DMD's persistent memory of defensive filters for the stack is cleared.
• Additional defensive filters cannot be added to this stack.

Tips:
• If you cannot update your DMD configuration file, you can issue the MODIFY FORCE_INACTIVE command for the DMD to disable defensive filtering for the stack. However, a later MODIFY REFRESH command will use the DMD configuration file, so if you want defensive filtering to remain disabled, you should update the DMD configuration file as soon as possible.
• Removing the DmStackConfig statement from the DMD configuration file does not delete existing defensive filters from the stack. If you remove the DmStackConfig statement, the defensive filters remain in the stack until they expire. To remove the defensive filters from the stack immediately, add the DmStackConfig statement back to the DMD configuration file and specify mode Inactive, or issue the MODIFY FORCE_INACTIVE command for the stack.

Relationship between intrusion detection services and defensive filters

Communication Server's intrusion detection services (IDS) support enables you to detect scans of your TCP/IP stack and possible attacks. It also provides traffic regulation for TCP connections and UDP sockets. One action that can be taken when a scan or attack is detected, or traffic regulation is enforced, is to generate a message to report the event.
An external security information and event manager that is configured to receive messages from the TCP/IP stack’s IDS function can analyze the messages and correlate the information with other information that it has received. Communication Server’s IDS messages can be one of a number of inputs that an external security information and event manager uses to make the decision to add a defensive filter to the stack. If the external security information and event manager detects an attack, it can add defensive filters to the stack to block the attack. Defensive filter support can be enabled without enabling Communication Server’s IDS support.

For more information about IDS support, see Chapter 16, “Intrusion detection services,” on page 823.

**Comparison of IP security filters and defensive filters**

Table 57 on page 1084 compares IP security filters and defensive filters.

</tbody>
</table>

The DMD run-time environment

The DMD is a z/OS UNIX application; it requires the z/OS UNIX file system. You can start the DMD from an MVS started procedure, from the z/OS UNIX shell, with the AUTOLOG statement in the TCP/IP profile, or by using the COMMDxx member of parmlib. The DMD must be started by a RACF-authorized user ID, and it must be in an APF-authorized library. For more information about how to start the DMD, see “Starting the DMD” on page 1090.

The DMD uses the MVS operator’s console, syslogd, CTRACE, and STDOUT for its logging and tracing. The MVS operator’s console and STDOUT are used for major events such as initialization, termination, and error conditions. Syslogd is used for logging events related to the processing of defensive filter requests. CTRACE is used for detailed tracing and debugging.
The DMD uses a standard message catalog. The message catalog must be in the UNIX file system. The directory location for the message catalog path is set by the environment variables NLSPATH and LANG.

The DMD and Language Environment run-time options

When you start the DMD from a started or cataloged procedure, you typically start it directly from the SEZALOAD data set using PGM=EZADMD. However, you can also start the DMD using BPXBATCH.

When you start the DMD using PGM=EZADMD, the STDENV DD card, if used, is passed directly to the DMD. Language Environment does not have access to the STDENV environment variables. As a result, any Language Environment run-time options set in the STDENV DD data set using the _CEE_RUNOPTS environment variable are ignored. In this case, Language Environment run-time options must be passed on the PARM parameter, and the options must be specified before any DMD options. However, the PARM parameter allows a maximum of 100 characters. If the Language Environment run-time options plus the DMD parameters that you want to specify exceed 100 characters, consider using BPXBATCH to start the DMD. When you use PGM=BPXBATCH to start the DMD, you can include the Language Environment variable _CEE_RUNOPTS on the STDENV DD card to specify run-time options in excess of 100 characters long.

For more information about how to start the DMD, see “Starting the DMD” on page 1090.

Enabling defensive filtering

To enable defensive filtering, first take both of the following actions:

- Enable the IP security function.
  
  See “Enabling the IP security function” on page 1087.

- Configure the Defense Manager daemon (DMD).
  
  See “Steps for configuring the DMD” on page 1088.

After configuring the DMD and enabling IP security, start the DMD. For details, see “Starting the DMD” on page 1090.

Enabling the IP security function

The IP security function must be enabled for defensive filters to be installed in a stack. If you do not have the IP security function enabled and want to use defensive filters, perform the following steps.

1. Specify the IPSECURITY parameter on the IPCONFIG statement in the TCP/IP profile.
2. If you have IPv6 traffic in your network and want to use defensive filters for IPv6, specify the IPSECURITY parameter on the IPCONFIG6 statement in the TCP/IP profile.
3. Configure a default IP security filter policy in the TCP/IP profile using the IPSEC statement in the TCP/IP profile.

  **Tip:** To permit all IPv4 traffic, you can configure a single rule for the IPSEC statement that allows all traffic. The following example allows all IPv4 traffic, without logging filter matches.

<table>
<thead>
<tr>
<th>IPSEC</th>
<th>Rule</th>
<th>SourceIp</th>
<th>DestIp</th>
<th>Logging</th>
<th>Prot</th>
<th>SrcPort</th>
<th>DestPort</th>
<th>Routing</th>
<th>Secclass</th>

<td>ROUTING EITHER</td>
</tr>
<tr>
<td></td>
<td>ENDIPSEC</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

For more information about the IPSEC statement, see z/OS Communications Server: IP Configuration Reference.

4. Optionally, configure a more comprehensive IP security policy in a flat file for the Policy Agent to install and manage.
You can configure IPSec encryption and authentication only in a Policy Agent flat file.

**Tip:** You can use the IBM Configuration Assistant for z/OS Communications Server to create an IP security policy flat file.

For more information about configuring an IP security policy, see Chapter 14, “Policy-based networking,” on page 761 and Chapter 17, “IP security,” on page 855.

**Attention:** You must configure an IP security policy if you enable the IP security function. If you specify IPSECURITY in your TCP/IP profile and do not configure an IP security policy, all inbound and outbound traffic will be discarded.

**Steps for configuring the DMD**

The Defense Manager daemon (DMD) plays an integral role in managing defensive filters, and must be active for defensive filters to be added, updated, or deleted.

**Procedure**

Perform the following steps to configure the DMD:

1. Authorize the DMD to the external security manager.
   
   See “Steps for authorizing resources for the DMD and the ipsec command” on page 1090.

2. Create the directories that the DMD needs.
   
   a) Create the directory /var/dm for use by the DMD. The DMD user ID must have permission to create, delete, read, and write files to this directory.
   
   b) If you set the PID file location with the DMD_PIDFILE environment variable, ensure that the path portion of the file name exists and that the DMD user ID has permission to create and write files to that directory. If you use the default PID file location, /var/dm/dmd.pid, you have already created the directory and given the DMD user ID the appropriate access in the previous step.
   
   c) Create the directory that will hold the persistent defensive filters for each stack, as well as the global defensive filters.

   The DMD configuration file parameter DefensiveFilterDirectory points to this directory. The default value is /var/dm/filters. Ensure that the DMD user ID is authorized to create, delete, read from, and write to files in this directory. The directory should have sufficient space to support at least 1 MB of data for each TCP/IP stack, plus another 1 MB for the global filter definitions. For more information about the DefensiveFilterDirectory parameter in the DMD configuration file, see z/OS Communications Server: IP Configuration Reference.

3. Create the DMD configuration file.

   Take one of the following actions:

   - Use the IBM Configuration Assistant for z/OS Communications Server.

     The IBM Configuration Assistant for z/OS Communications Server, an optional GUI-based tool, provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the IBM Configuration Assistant for z/OS Communications Server to generate the DMD configuration file.

     The IBM Configuration Assistant for z/OS Communications Server is a z/OS Management Facility (z/OSMF) task. z/OSMF provides a web browser interface for a variety of z/OS system management functions. When you invoke the IBM Configuration Assistant for z/OS Communications Server in z/OSMF, the IBM Configuration Assistant for z/OS Communications Server runs natively in the z/OS system and you can access it through a web browser.

     Through a series of wizards and online help panels, you can use the GUI to create DMD configuration files for any number of z/OS images with any number of TCP/IP stacks per image.

   - Configure the file manually.

     A sample configuration file is in /usr/lpp/tcpip/samples/dmd.conf.
For a description of the DMD configuration file, see z/OS Communications Server: IP Configuration Reference.

If the DMD was defined to the external security manager with a nonzero UID, ensure that the DMD has permission to read the configuration file. The DMD user ID must have both read access to the configuration file and execute access to the directory containing the configuration file.

**Tip:** You can create the configuration file in the /var/dm directory and use the DMD_FILE environment variable to specify the configuration file. You set up the /var/dm directory in step 2 to allow DMD to create, delete, read, and write files to this directory.

The following search order is used by the DMD to locate the configuration data set or file:

a. If the environment variable DMD_FILE is defined, the DMD uses the value as the name of an MVS data set or z/OS UNIX file to access the configuration data.

b. /etc/security/dmd.conf

You can specify statements in the configuration file using a variety of EBCDIC code pages. Use the DMD_CODEPAGE environment variable to specify the code page that you want to use. The default code page is IBM-1047.

4. Optionally, set the _BPX_JOBNAME environment variable.

When you start the DMD from the z/OS UNIX shell, set the environment variable _BPX_JOBNAME. This enables a specific job name to be used with the STOP or MODIFY console commands. For information about _BPX_JOBNAME, see z/OS UNIX System Services Planning.

5. Configure and start syslogd.

The DMD uses the local4 facility when writing messages to syslogd. For performance purposes, syslogd should use z/OS File System as its underlying file system. For more information about syslogd, see "Configuring the syslog daemon" on page 199.

6. Optionally, update the DMD environment variables.

The DMD uses the following environment variables. You can modify them for your installation.

**DMD_CODEPAGE**

Use the DMD_CODEPAGE variable to specify the EBCDIC code page to be used when reading the configuration file. For details about the supported code pages, see z/OS Communications Server: IP Configuration Reference.

**DMD_CTRACE_MEMBER**

Used by the DMD to locate a parmlib member for DMD CTRACE customization. For more information about the TCP/IP services component trace for the DMD, see z/OS Communications Server: IP Diagnosis Guide.

**DMD_FILE**

Used by the DMD in the search order for the DMD configuration file. For details about the search order used for locating this configuration file, see step "3" on page 1088.

**DMD_PIDFILE**

Used by the DMD in the search order for the file that should contain the DMD process ID (PID). The search order for the DMD PID file is as follows:

a. DMD_PIDFILE environment variable

b. /var/dm/dmd.pid

7. If you are starting the DMD as a started procedure, update the DMD cataloged procedure.

Create the cataloged procedure by copying the sample in SEZAINST(DMD) to your system. Specify the DMD parameters and change the data set names to suit your local configuration. A copy of the DMD cataloged procedure can also be found in z/OS Communications Server: IP Configuration Reference.

If the DMD was defined to the external security manager with a nonzero UID and the cataloged procedure specifies an HFS file containing environment variables, ensure that the DMD has permission to read the HFS file.
Steps for authorizing resources for the DMD and the ipsec command

You need to define and authorize the DMD user ID, permit the DMD user ID to SYS1.PARMLIB, and define the SERVAUTH profiles necessary to be able to add, update, delete, and display defensive filters.

Before you begin
RACF is used as the external security manager in the following examples. However, you can use any SAF-compliant security product. RACF commands shown in these examples are also provided in the EZARACF member of the SEZAINST data set. In these examples, it is assumed that the DMD is running under the user ID DMD.

Procedure
Perform the following steps to authorize access to the appropriate resources:

1. Define and authorize the DMD user ID.
   The DMD is a z/OS UNIX application that you can start from the z/OS UNIX shell or from an MVS started procedure. Before starting the DMD, you must define the DMD user ID to the external security manager. If you start the DMD from an MVS started procedure, the DMD user ID must also be authorized to the STARTED class. In the following example, the DMD user ID is defined with UID 0:

   ```
   ADDUSER DMD DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(0) HOME('/'))
   RDEFINE STARTED DMD.*            STDATA(USER(DMD))
   SETROPTS RACLIST(STARTED) REFRESH
   SETROPTS GENERIC(STARTED) REFRESH
   ```
   You can define the DMD with a nonzero UID. For additional steps that you must take when the DMD UID is nonzero, see “Steps for configuring the DMD” on page 1088.

2. Permit the DMD user ID to SYS1.PARMLIB.
   The DMD uses the TCP/IP component trace (CTRACE) to perform service-level tracing. The default DMD component trace parmlib member is stored in SYS1.PARMLIB. The DMD user ID must be permitted to access SYS1.PARMLIB.
   Issue the following command:

   ```
   PERMIT   SYS1.PARMLIB  ID(DMD) ACCESS(READ)
   ```

3. Define SERVAUTH profiles to control the users that are allowed to manage defensive filters.
   For information about defining the SERVAUTH profiles needed for a user to be able to add, update, delete, and display defensive filters, see “Step 4: Authorizing the ipsec command to the external security manager” on page 1333. Additional information about command security and the SERVAUTH profile is available in z/OS Communications Server: IP System Administrator’s Commands.

Starting the DMD

You can start DMD in any of the following ways:

- By using an MVS procedure from the MVS operator console. A sample start procedure is provided in SEZAINST(DMD).
- By issuing the `dmd` command from the z/OS UNIX shell.
- By using the `COMMNDxx` member of parmlib. This member enables the DMD to be automatically started after an IPL of the system. For information about configuring and using the `COMMNDxx` member of parmlib, see z/OS MVS Initialization and Tuning Reference.
• By using the AUTOLOG statement in the TCP/IP profile. For information about the AUTOLOG statement, see z/OS Communications Server: IP Configuration Reference.

Tips:
• Do not start the DMD using the AUTOLOG statement in a stack’s profile if you are running in a CINET environment with more than one stack configured. If a stack is configured using AUTOLOG to start and stop the DMD each time the stack starts and stops, it is difficult to maintain a stable running instance of the DMD in a multi-stack environment. In a multi-stack environment, you should use another method to automate starting the DMD when the system is started, such as using the COMMNDxx member of parmlib.
• When you start the DMD from an MVS procedure, set the environment variables using the STDENV DD statement in the DMD procedure.
• If you start the DMD from the z/OS shell and you stop the shell environment from scrolling, when the daemon needs to display data to the shell, it might stop and wait indefinitely for the shell to scroll and make output buffer space available for the data.

Restriction: Only one instance of the DMD can run on a z/OS image. If you attempt to start a second instance, the second DMD will fail.

Stopping the DMD

Stop the DMD in one of the following ways:
• From MVS, stop the DMD by issuing the following command:

```
STOP procname
```

where procname is one of the following values:

- If the DMD was started from a cataloged procedure, the procname value is the member name of that procedure.
- If the DMD was started from the z/OS UNIX shell and the environment variable _BPX_JOBNAME was set, the procname value is the same as the _BPX_JOBNAME value.
- If the DMD was started from the z/OS UNIX shell and _BPX_JOBNAME was not set, the procname value is based on the userid. If the userid is 8 characters long, the procname is the userid. If the userid is less than 8 characters long, the procname is useridX, where X is the sequence number that is set by the system. To determine the sequence number, from the ISPF LOG window on TSO, issue the following command:

```
/d omvs,u=userid
```

This command displays the programs that are running under the specified user ID. For more information about _BPX_JOBNAME, see z/OS UNIX System Services Planning.
• From the z/OS shell, issue the kill command from a superuser ID for the process ID (PID) that is associated with the DMD. By default, the DMD PID is recorded in /var/dm/dmd.pid. You can change the default location using the DMD_PIDFILE environment variable.

Using the DMD MODIFY command

The DMD provides a MODIFY command to take the following actions:

• Reread the configuration file.

Use the MODIFY procname,REFRESH command to reread the DMD configuration file. You can use this command to update some DMD configuration file parameters. For information about the DMD configuration file parameters that can be dynamically changed, see z/OS Communications Server: IP Configuration Reference.
• Display the configuration file parameters.
  Use the MODIFY procname,DISPLAY command to display configuration values currently in use by the DMD.

• Disable defensive filtering.
  Use the MODIFY procname,FORCE_INACTIVE,stackname command to disable defensive filtering for stack stackname. All defensive filters for the stack are removed from the DMD's persistent memory and from the stack. No additional defensive filters are added to the stack while the stack's mode is inactive. The change to the stack's mode persists until the next successful MODIFY procname,REFRESH command.

For more information about the MODIFY command for DMD, see z/OS Communications Server: IP System Administrator’s Commands.
Chapter 20. Application Transparent Transport Layer Security data protection

The Transport Layer Security (TLS) protocol defined in RFC 2246 provides communications privacy over the Internet. The protocol enables client and server applications to communicate in a way that is designed to prevent eavesdropping, tampering, and message forgery. To implement TLS protocols, typically, applications must be modified to incorporate a TLS toolkit. Modifying applications requires significant development overhead, ongoing maintenance for each application, and application-specific knowledge of the parameters needed to implement TLS for that application.

Application Transparent Transport Layer Security (AT-TLS) consolidates TLS implementation in one location, reducing or eliminating application development overhead, maintenance, and parameter specification. AT-TLS is based on z/OS System SSL, and transparently implements these protocols in the TCP layer of the stack. As shown in Figure 133 on page 1093, most applications do not need any awareness of the security negotiations and encryption done by TCP/IP on its behalf. However, you might want some applications to be aware of AT-TLS or have control over the security functions being performed by TCP/IP. For example, if the application is a server requesting client authentication, you might want the application to get the partner certificate or the user ID associated with the partner certificate, or the application might negotiate in cleartext with its partner to decide whether a secure session is necessary. If both agree to a secure session, the application needs to tell AT-TLS to set up a secure session. The SIOCTTLSCTL ioctl provides the interface for the application to query or control AT-TLS.

In all cases, an application using a socket enabled with AT-TLS continues to send and receive text data in the clear while encrypted data flows over the network. This allows the use of TLS with applications that cannot be modified or that cannot incorporate one of the available tool kits. The partner application must also support TLS protocols, either by using AT-TLS or an available TLS toolkit.

Figure 133. Application Transparent TLS

AT-TLS configuration in PROFILE.TCPIP

AT-TLS support is controlled by the TTLS or NOTTLS parameter on the TCPCONFIG statement in PROFILE.TCPIP. AT-TLS is enabled by specifying TTLS. The information required to negotiate secure connections is provided to the stack by AT-TLS policies configured in Policy Agent. When AT-TLS is enabled and a newly established connection is first used, the TCP layer of the stack searches for a matching AT-TLS policy installed from the Policy Agent. If no policy is found, the connection is made without AT-TLS involvement.

TCP/IP stack initialization access control

A TCP/IP stack initializes before Policy Agent installs configured policies into the stack. This leaves a window of time where connections that should be covered by AT-TLS are clear text connections. The RACF resource EZB.INITSTACK.sysname.tcpname in the SERVAUTH class is used to block stack access, except for the user IDs permitted to the resource. While in this initialization window, any socket request from an unauthorized application receives the same errno (EAGAIN with JrTcpNotActive) received prior to the stack coming up.

Checking is done only if the TCP/IP profile activates AT-TLS. If there is no profile in the SERVAUTH class covering this resource name, all socket requests fail, including those from Policy Agent. Checking ceases the first time that the Policy Agent indicates AT-TLS policy is complete, or if a TCP/IP profile change deactivates AT-TLS.

When the limited access window begins, non-scrollable message EZZ4248E is written to the system console stating that TCP/IP is waiting for Policy Agent to install AT-TLS policies. The message is released when the restriction ends. You can delay the start of AUTOLOG procedures during this window of time by specifying the optional DELAYSTART parameter with the TTLS subparameter on the AUTOLOG entry for that procedure; when specified, the procedure will start after the EZZ4248E message is deleted and message EZZ4250I is issued indicating that AT-TLS services are available.

You must permit a limited set of administrative applications to the profile to ensure full initialization of the stack. If Policy Agent is dependent on other applications in your environment, they must also be permitted. You can permit other applications that do not require AT-TLS and that you want to start prior to general applications. At a minimum, the following applications should be permitted to the profile:

- Policy Agent
- OMPROUTE
- SNMP agent and subagents
- NAMED

For examples of the security product commands needed to create this resource profile name and grant users access to it, see member EZARACF in sample data set SEZAINST.

Options for configuring AT-TLS security

AT-TLS is configured using a set of configuration statements and parameters coded into a flat file, which is parsed by the Policy Agent to establish the AT-TLS policy for each TCP/IP stack. In a complex environment, this file can become large. For this reason, there are two alternatives for creating the Policy Agent files.

Option 1: Use the IBM Configuration Assistant for z/OS Communications Server

The IBM Configuration Assistant for z/OS Communications Server, an optional GUI-based tool, provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the IBM Configuration Assistant for z/OS Communications Server to generate the Policy Agent files.
The IBM Configuration Assistant for z/OS Communications Server is a z/OS Management Facility (z/OSMF) task. z/OSMF provides a web browser interface for a variety of z/OS system management functions. When you invoke the IBM Configuration Assistant for z/OS Communications Server in z/OSMF, the IBM Configuration Assistant for z/OS Communications Server runs natively in the z/OS system and you can access it through a web browser.

Through a series of wizards and online help panels, you can use the IBM Configuration Assistant for z/OS Communications Server to create AT-TLS configuration files for any number of z/OS images with any number of TCP/IP stacks per image. Using the IBM Configuration Assistant for z/OS Communications Server, there are three types of reusable objects:

• Traffic descriptors that define the local application, by describing the TCP traffic with ports or identifying the application using its jobname.

• Security levels that define the different ways to protect data, such as the encryption level.

• Requirement maps that map traffic descriptors to security levels. A single requirement map should contain a complete set of security requirements that will govern the level of security for multiple IP traffic types.

For each TCP/IP stack, you create a set of connectivity rules that indicate the data endpoints and indicate which requirement map will govern security between the data endpoints.

The IBM Configuration Assistant for z/OS Communications Server comes with a number of IBM-supplied traffic descriptors, security levels, and requirement maps that are easily applied, or you can use the IBM-supplied definitions as the basis for your own set of reusable objects.

The IBM Configuration Assistant for z/OS Communications Server can dramatically reduce the amount of time that is required to create AT-TLS policy files, contributing to ease of configuration and maintenance. Because of the inherently complex nature of z/OS security, using the GUI can help you ensure that you have a consistent and easily manageable interface for implementing AT-TLS security.

This information primarily describes option 2, manual configuration. However, if you are using the IBM Configuration Assistant for z/OS Communications Server, reading this information will help you understand security concepts and the relationship between Policy Agent and AT-TLS function.

**Option 2: Manual configuration**

You can manually create the AT-TLS policy configuration files by coding all the required statements in a z/OS UNIX file or MVS data set. There are a large number of configuration options provided by AT-TLS policy statements that permit advanced users to carefully fine-tune AT-TLS policy on a per-stack basis. This information describes the procedure for creating an AT-TLS policy by manually creating and editing the configuration files. For details about the AT-TLS policy statements, see z/OS Communications Server: IP Configuration Reference.

**Specifying the AT-TLS configuration file based on Policy Agent role**

The Policy Agent can act as a policy server, a policy client, or neither. For more information on these different roles, see “Policy types and infrastructure overview” on page 761. Regardless of which option is used to configure AT-TLS policies, the resulting configuration files need to be specified using different statements, depending on the role of the Policy Agent.

• If you are using the Policy Agent as a policy client that retrieves AT-TLS policies from the policy server, specify the configuration files using the DynamicConfigPolicyLoad statement on the policy server.

• If you are using the Policy Agent as a policy client, but the policy client does not retrieve AT-TLS policies from the policy server, specify the configuration files using the TTLSCConfig statement on the policy client.

• If you are not using a policy client/policy server environment, specify the configuration files using the TTLSCConfig statement on the single Policy Agent.

When this information refers to configuration files, keep in mind where the files should exist, based on the role of the Policy Agent.
AT-TLS policy configuration

AT-TLS policy is provided to the stack by the Policy Agent. The Policy Agent main configuration file contains a TcpImage statement for each stack that is to receive policy, and can optionally contain a CommonTTLSConfig statement that identifies a local shared AT-TLS policy file.

The TcpImage statement identifies the z/OS UNIX file or MVS data set that contains policy for that stack. This policy file can contain a TTLSConfig statement to identify the z/OS UNIX file or MVS data set that contains the local AT-TLS policy. The TTLSConfig statement is required for each stack that is to receive AT-TLS policy. If both a TTLSConfig statement and a CommonTTLSConfig statement are defined, the specified CommonTTLSConfig file is processed before the TTLSConfig policy file specified for that stack.

On the policy server, use the DynamicConfigPolicyLoad statement to specify the remote AT-TLS policies. On the policy client, use the PolicyServer statement to retrieve the remote AT-TLS policies from the policy server.

Within the AT-TLS policy file, AT-TLS rules define a set of conditions that are compared to connections when policy is mapped during connect, or at the first select for readable or writable, poll for readable or writable, send, receive, or SIOCTTLSCTL ioctl. If a rule match is found, AT-TLS transparently provides TLS protocol control for the connection based on the security attributes specified in the actions associated with the rule.

AT-TLS rules

A TTLSRule statement consists of a set of conditions that are compared against the connection being checked. When a match is found, policy lookup stops and the connection is assigned the actions associated with the rule. The rule conditions are:

- LocalAddr - Local IP address or addresses
- RemoteAddr - Remote IP address or addresses
- LocalPortRange - Local port or ports
- RemotePortRange - Remote port or ports
- Jobname - Job name of the owning application or wildcard job name
- Userid - User ID of the owning process or wildcard user ID
- Direction - Inbound if applied to a passive socket (established by accept), Outbound if applied to an active socket (established by connect), or Both

Direction and at least one other condition must be specified. Other rule considerations include:

- If a condition is not specified, that condition is not considered when comparing the rule and the connection for a match.
- Multiple values can be specified for the IP address and port conditions, either directly in the condition or as a referenced group.
- IPv6 addresses are valid in all environments.

Each TTLSRule statement can also have a priority. Priority values can be integers in the range 1 - 2000000000, with 2000000000 being the highest priority. When assigning priorities, you should skip some values to allow for future rule insertion between existing rules. Policy Agent orders rules in alphabetical order within priority.

Tip: If connections can map to more than one rule, always use priority and leave priority space between rules.

AT-TLS actions

A TTLSRule statement can reference up to three actions:

- The TTLSGroupActionRef parameter includes the name of a globally defined TTLSGroupAction statement
• The TTLSEnvironmentActionRef parameter includes the name of a globally defined TTLSEnvironmentAction statement

• The TTLSConnectionActionRef parameter includes the name of a globally defined TTLSConnectionAction statement

The TTLSGroupActionRef parameter is required, and the TTLSGroupAction statement must specify TTLSEnabled ON or TTLSEnabled OFF. If TTLSEnabled OFF is specified, no additional specifications are needed. Otherwise, the AT-TLS environment action is required and the AT-TLS connection action is optional. Each action represents a scope of control.

When an AT-TLS action statement is deleted or replaced, it is considered stale. New connections will not map to a stale action. Connections that mapped to an action that later becomes stale continue to use the resources associated with the stale action until the connection closes.

**AT-TLS group action**

This action defines whether AT-TLS is enabled, allows trace settings, and provides the ability to set unique Language Environment variables for the Language Environment process that will be started for the action. Many TTLSRule statements can reference the same TTLSGroupAction statement. In a simple implementation of AT-TLS, you need to specify only TTLSEnabled ON on the TTLSGroupAction statement.

The AT-TLS group action represents a single Language Environment process and enclave, and initializes one instance of the System SSL DLL. Global attributes are owned by this action. Each AT-TLS group has a main task, a logging task, and a dynamic pool of pthreads that handle System SSL secure environment and secure connection management. When a stale group has no remaining connections, the pthreads, tasks, and Language Environment process are removed.

**Guideline:** Use as few AT-TLS group actions as necessary.

**AT-TLS environment action**

This action requires a key ring name (either RACF or gskkyman format), and the handshake role (client or server) this half of the connection will assume. Cipher suites and trace settings can also be set. There are several advanced parameters available if needed, but in a simple implementation of AT-TLS, you need to specify only a key ring and the handshake role.

The AT-TLS environment action is used to create System SSL environments. A key ring and SSL Session ID (SID) cache are examples of attributes owned by a System SSL environment. The AT-TLS environment action initializes a System SSL environment within the Language Environment process that was created to represent an AT-TLS group action. Several System SSL environments can exist within a single AT-TLS group. The same TTLSEnvironmentAction statement can be used to create similar System SSL environments in the same or different groups. AT-TLS dynamically creates instances of System SSL environments as needed. AT-TLS deletes System SSL environments when they have had no connections using them for a period of ten to twenty minutes. If the TTLSEnvironmentAction statement used to create a System SSL environment becomes stale, AT-TLS deletes the environment when it has no remaining connections. Connections associated with the same server application or same client user ID can share a System SSL environment. Connections that share an existing System SSL environment avoid the processing required to initialize an environment, such as opening a key ring. Connections between the same partners can also reuse recent session information in the SID cache, allowing them to use the SSL short handshake that requires less processing. System SSL connection resources are released when the connection closes.

**AT-TLS connection action**

The AT-TLS connection action represents attributes at the connection level. This action is optional, and is needed only when a subset of connections within an AT-TLS environment must have different parameters. Handshake role, security version, cipher suites, and tracing are examples of attributes that can be changed at the connection level. In a simple implementation of AT-TLS, you do not need to specify this action.
System SSL connections are initialized within a System SSL environment. Use the AT-TLS connection action to override attributes specified at the SSL environment layer. System SSL connection resources are released when the connection closes.

**Getting started with AT-TLS**

Assume you have a TCP client and server application pair running on z/OS platforms. This application handles sensitive data, and you want this application to be used only with the TLS protocol. The server application runs under the job name of XYZSRV, and creates a passive TCP socket bound to IP address INADDR_ANY and port 5000. The client application runs as a command, issued by TSO or z/OS UNIX interactive users, and connects to port 5000.

To complete AT-TLS security setup for this sample environment, you need to create both server and client key rings. The server key ring needs to contain a server certificate, and any certificates used to sign it. The server needs access to the private keys of the server certificate. The client key ring needs the root certificate used to sign the server certificates. For a TLS/SSL primer and some step-by-step examples, see Appendix B, “TLS/SSL security,” on page 1299. For more information on managing key rings and certificates with RACF and the RACDCERT command, see z/OS Security Server RACF Administrator’s Guide. For detailed information on managing key rings and certificates with gskkyman, see z/OS Cryptographic Services System SSL Programming.

**Configuring the server system**

On each z/OS system where you run the server application, see Table 58 on page 1098 for the tasks needed to configure the server.

<table>
<thead>
<tr>
<th>Task</th>
<th>Specification</th>
</tr>
</thead>
<tbody>
<tr>
<td>Create key ring</td>
<td>Create server key ring with server certificate and necessary certificate authority certificates.</td>
</tr>
</tbody>
</table>
| Create Policy Agent files     | 1. Create a Policy Agent main configuration file containing a TcpImage statement for the server stack.  
                                | 2. Create a Policy Agent image configuration file for the server stack.  
                                | 3. If AT-TLS policies are to be retrieved from the policy server, create image-specific AT-TLS configuration files, and optionally, common AT-TLS configuration files, on the policy server. |
### Table 58. AT-TLS configuration for the server system (continued)

<table>
<thead>
<tr>
<th>Task</th>
<th>Specification</th>
</tr>
</thead>
</table>
| Add AT-TLS configuration                  | 1. For local AT-TLS policies, add a `TTLSCfg` statement to the Policy Agent image configuration file, identifying the `TTLSCfg` policy file location:  
   ```
   TTLSCfg serverpath
   ```  
   2. For remote AT-TLS policies, add a `PolicyServer` statement to the policy client image configuration file:  
   ```
   PolicyServer
   {
   ClientName name
   PolicyType TTLS
   {
   ...
   }
   }
   ```  
   Add a `DynamicConfigPolicyLoad` statement to the policy server main configuration file:  
   ```
   DynamicConfigPolicyLoad clientname
   {
   PolicyType TTLS
   {
   PolicyLoad serverpath
   }
   }
   ```  
| Add statements to the AT-TLS policy file  | Add the AT-TLS policy statements to the `serverpath` file:  
   ```
   TTLSRule XYZServerRule
   {
   LocalPortRange 5000
   JobName XYZSRV
   Direction Inbound
   TTLSGroupActionRef XYZGroup
   TTLSEnvironmentActionRef XYZServerEnvironment
   }
   TTLSGroupAction XYZGroup
   {
   TTLSEnabled On
   }
   TTLSEnvironmentAction XYZServerEnvironment
   {
   TTLSKeyRingParms
   {
   Keyring server_key_ring
   }
   HandshakeRole SERVER
   Trace 7
   }
   ```  
| Set up InitStack access control           | 1. Define the EZB.INITSTACK.sysname.tcpname profile for each AT-TLS stack.  
   2. Permit administrative applications to use the stack before AT-TLS is initialized.  
   For examples of the security product commands needed to create this resource profile name and grant users access to it, see member EZARACF in sample data set SEZAINST.

Configuring the client systems

On each z/OS system where you run the client application, see Table 59 on page 1100 for the tasks needed to configure the client.

Table 59. AT-TLS configuration for the client system

<table>
<thead>
<tr>
<th>Task</th>
<th>Specification</th>
</tr>
</thead>
</table>
| Create key ring     | Create a client key ring for each client with necessary certificate authority certificates. If using client authentication, also attach each client's certificate to their key ring. **Tips:**  
  • To simplify AT-TLS policy, use the same RACF key ring name for every client. SystemSSL will qualify the key ring name with the current user ID when accessed.  
  • Because a copy of the specified key ring contents is loaded into TCPIP private storage for each user, keep a minimal number of certificates connected to the keyring. |
| Create Policy Agent files | 1. Create a Policy Agent main configuration file containing a TcpImage statement for the client stack.  
  2. Create a Policy Agent image configuration file for the client stack.  
  3. If AT-TLS policies are to be retrieved from the policy server, create image-specific AT-TLS configuration files, and optionally, common AT-TLS configuration files, on the policy server. |
<table>
<thead>
<tr>
<th>Task</th>
<th>Specification</th>
</tr>
</thead>
</table>
| **Add AT-TLS configuration** | 1. For local AT-TLS policies, add a `TTLSCfg` statement to the Policy Agent image configuration file, identifying the `TTLSCfg` policy file location:  
\[
\text{TTLSCfg \hspace{1em} clientpath}
\]
2. For remote AT-TLS policies, add a `PolicyServer` statement to the policy client image configuration file:  
\[
\text{PolicyServer}\{ \\
\hspace{1em} \text{ClientName name} \\
\hspace{1em} \text{PolicyType TTLS} \\
\hspace{1em} \{ \\
\hspace{1em}\hspace{1em} \} \\
\hspace{1em}\} \\
\}
\]
Add a `DynamicConfigPolicyLoad` statement to the policy server main configuration file:  
\[
\text{DynamicConfigPolicyLoad \hspace{1em} clientname}\{ \\
\hspace{1em} \text{PolicyType TTLS} \\
\hspace{1em} \{ \\
\hspace{1em}\hspace{1em} \text{PolicyLoad clientpath} \\
\hspace{1em}\} \\
\hspace{1em}\} \\
\}
\]

| **Add statements to the AT-TLS policy file** | Add the AT-TLS policy statements to the `clientpath` file:  
\[
\text{TTLSRule XYZClientRule}\{ \\
\hspace{1em} \text{RemotePortRange 5000} \\
\hspace{1em} \text{Direction Outbound} \\
\hspace{1em} \text{TTLSGrpActionRef XYZGroup} \\
\hspace{1em} \text{TTLSEnvironmentActionRef XYZClientEnvironment} \\
\}
\]

| **Set up InitStack access control** | 1. Define the `EZB.INITSTACK.sysname.tcpname` profile for each AT-TLS stack.  
2. Permit administrative applications to use the stack before AT-TLS is initialized.  
For examples of the security product commands needed to create this resource profile name and grant users access to it, see member EZARACF in sample data set SEZAINST.  

| **Enable AT-TLS** | Set TCPCONFIG TTLS in PROFILE.TCPIP. |
Steps for starting AT-TLS and verifying its operation

After configuring the server and client systems, use these steps to start and verify AT-TLS.

Before you begin

• Perform the tasks in AT-TLS configuration for the server system and AT-TLS configuration for the client system.
• Review your syslogd configuration to verify that messages written by Policy Agent and TCP/IP stacks are saved in the wanted files. AT-TLS syslogd messages are written to the daemon facility by default.
• Start syslogd.

You are now ready to start the sample AT-TLS environment and verify its operation.

Procedure

Perform the following steps to start AT-TLS and verify its operation:

1. Start the TCP/IP stacks.
2. Start the administrative applications required to successfully run Policy Agent, such as OMPROUTE and LDAP.
3. If System SSL needs to access Integrated Cryptographic Services Facility (ICSF), start ICSF. For information about using cryptographic features with System SSL, see z/OS Cryptographic Services System SSL Programming.
4. Start Policy Agent on all participating systems and verify that there were no policy errors in processing the policy files.
5. Verify that the participating TCP/IP stacks have received AT-TLS policy and released console message EZZ4248E.
6. Start server application and verify that it starts without errors.
7. Start client applications. Review the AT-TLS trace messages in the syslogd output on both the client and server systems. Verify that connections are mapping to the intended policy and no handshake errors occur. The info messages EZD1281I TTLS Map and EZD1283I TTLS Initial Handshake show the policy used and result of TLS handshake negotiation. The error message EZD1286I TTLS Error shows any failures.

Results

For information on common AT-TLS startup errors, see z/OS Communications Server: IP Diagnosis Guide.

Application compatibility with AT-TLS

Most applications can use AT-TLS. However, some applications should not be configured to use AT-TLS. Any application that is already configured to use SSL or TLS protocols should not use AT-TLS. Use of AT-TLS would result in encrypting data that is already encrypted. The receiving partner would not be able to decipher the data that had been encrypted twice. If the application can be configured to use clear text or the application uses the SIOCTTLSCTL ioctl, AT-TLS can provide support.

TCP/IP applications that already support the TLS protocol include:

• TN3270E Telnet server
  Use the TTLSPort statement to configure the TN3270E Telnet server to support AT-TLS. See the information about configuring Telnet security using AT-TLS under “Transport Layer Security” on page 567.
• FTP server
  Code the TLSMECHANISM statement in FTP.DATA to configure the FTP server to support AT-TLS. See “Steps for migrating the FTP server and client to use AT-TLS” on page 678.
• FTP client

Code the TLSMECHANISM statement in FTP.DATA to configure the FTP client to support AT-TLS. See “Steps for migrating the FTP server and client to use AT-TLS” on page 678.

• DCAS (Express Logon server)

Code the TLSMECHANISM statement in the DCAS configuration file to configure the DCAS server to support AT-TLS. See “Customizing DCAS for TLS/SSL” on page 1286.

AT-TLS does not support web servers using the Fast Response Cache Accelerator (FRCA) support in TCP/IP. AT-TLS ignores policy for connections using FRCA. The sockets are treated as if they did not match any AT-TLS rules.

AT-TLS does not support applications that use the Pascal sockets API. AT-TLS ignores all Pascal sockets. The sockets are treated as if they did not match any AT-TLS rules. TCP/IP applications that use the Pascal API include:

• TSO TN3270E Telnet client
• LPD server

Policy considerations

Policy is a powerful tool for configuring and managing your applications that use AT-TLS. Before configuring the AT-TLS policy, review the general syntax rules in the Policy Agent and policy applications topic in z/OS Communications Server: IP Configuration Reference.

Reusable objects

With several of the AT-TLS rule conditions and action parameters, you can reference named objects. If you are going to use the same definition in several rules or actions, it is easier to create a single named object and refer to it, rather than repeating the definition. This also makes changing these definitions easier and more accurate. For example, the IpAddrGroup statement can be used to identify groups of IP addresses that are used in several rules. You might find it useful to define TTLSRule statements that reference an IP address group with a name, such as LocalHost. In each stack’s AT-TLS policy file, you would define that IP address group with all of the addresses local to that stack. That single reference can then be used throughout the policy to easily represent all local IP addresses, without re-coding the local addresses in each rule condition.

Common AT-TLS configuration file

The common AT-TLS configuration file should contain all of the policy that is common to multiple stacks. When the policy agent reads a policy file for a given stack, the contents of the common AT-TLS configuration file are logically added before the contents of the stack-specific file. Rules and actions in the common AT-TLS configuration file can reference objects, such as a local IpAddrGroup statement, that are defined in the stack-specific AT-TLS configuration file. Rules and actions in the stack-specific file can also reference objects that are defined in the common file.

If Policy Agent encounters multiple objects of the same type and name, the last occurrence is the one that is used. You can take advantage of this by defining an object that is used on many stacks in the common file, and then overriding it in the stack-specific file of a specific stack.

Exempting specific connections from AT-TLS

In some cases, you might want to have the majority of users of an application using AT-TLS, but then exempt a small group of users. You might find that it is simpler to define a broad AT-TLS policy for the application, and then define a higher priority rule for the exempt users. The simplest way to do this is to define a TTLSGroupAction statement with the TTLSEnabled parameter set to OFF. The exempt user rule would then reference this action. When the TTLSGroupAction statement specifies the TTLSEnabled parameter as OFF, the TTLSEnvironmentActionRef parameter on the corresponding rule is not required.
**Action refresh**

When Policy Agent is stopped and restarted, or when policy files are changed, policy objects that are currently in use might be deleted or replaced. When an AT-TLS action is deleted or replaced, connections using the old object continue processing without change. Connections that search AT-TLS policy after the change use the new action objects. A change to an AT-TLS group action causes a new Language Environment process to be created, along with new SSL environments for each user or application environment associated with that group. A change to an AT-TLS environment action causes new SSL environments to be initialized within each group with which that environment is associated. System SSL reopens key rings and certificates, and creates an empty session ID cache when it initializes an SSL environment.

There are cases when a change is made that is not reflected by a change in the action. For example, the default certificate in a key ring might change. The key ring name has not changed, but there is a need to open a new environment. Simply refreshing policy will not refresh the AT-TLS environment action in AT-TLS, because no values within the action have changed. To force a refresh in AT-TLS, some parameter must be changed. The EnvironmentUserInstance parameter can be used for this purpose. Incrementing the instance number forces a refresh of AT-TLS without changing any of the security parameters. Similarly, changes to the contents of the environment file named in a group action will not be applied until the group action is changed. The GroupUserInstance parameter can be used to force an AT-TLS refresh of the group, creating a new Language Environment process using the new environment file contents.

Sometimes after you have made a change to an AT-TLS policy, the changed policies are not automatically reinstalled by the Policy Agent; new connections might fail until the policies are reinstalled. If you see AT-TLS connection setup errors with message EZD1286I or EZD1287I after you made an AT-TLS configuration change, you can force all AT-TLS policies to be reinstalled by refreshing the Policy Agent. From the MVS console, issue the MODIFY procname,REFRESH command. For more information about controlling the refresh of polices using the TcpImage and PEPInstance statements, see z/OS Communications Server: IP Configuration Reference.

**Achieving the basic level of security**

To achieve the basic level of security, take the following actions:

1. Pick the handshake roles.
2. Specify the key ring.

**Picking the handshake roles**

Every secure connection must have one end using the HandshakeRole Client, and the other end using the HandshakeRole Server or HandshakeRole ServerWithClientAuth.

In the SSL and TLS protocols, the client side sends a ClientHello handshake record and the server side responds with a ServerHello handshake record. If both sides send ClientHello records, the handshake fails. If both sides wait for a ClientHello, the handshake times out.

The role played in the handshake is independent of whether the application is used as the client, server, or peer. It is also independent of which application does the listen() and accept() and which does the connect(). The primary consideration for deciding which role an application should play is certificate management.

- An application designated as HandshakeRole Server must have a user or site certificate on its key ring. It must have access to the private keys of its user or site certificate. It might also need other certificates on its key ring, required for authentication.

  The partner application designated as HandshakeRole Client must have a key ring that contains the root certificates required to authenticate the server's certificate. The client does not need access to the private keys of any certificate. Clients can share this key ring.
An application designated as HandshakeRole ServerWithClientAuth might need additional root certificates on its key ring to authenticate client certificates. The server decides whether a client must present a user certificate and what constitutes an acceptable certificate.

The partner application designated as HandshakeRole Client decides whether to present a user certificate when challenged. To present a user certificate, it must have a private key ring with that user certificate. It must have access to the private keys of the user certificate. The client key ring must also contain the root certificates required to authenticate the server’s certificate.

When the HandshakeRole parameter is set to ServerWithClientAuth, a certificate request is sent to the client during the handshake. The client can send its certificate to the server, which can then validate the certificate. The level of validation done by the server is controlled by the setting of the ClientAuthType parameter. The following chart summarizes the differences between the parameter settings:

<table>
<thead>
<tr>
<th><strong>ClientAuthType</strong></th>
<th><strong>Client certificate required or optional</strong></th>
<th><strong>Certificate validation</strong></th>
</tr>
</thead>
<tbody>
<tr>
<td>PassThru</td>
<td>Optional</td>
<td>None</td>
</tr>
<tr>
<td>Full</td>
<td>Optional</td>
<td>Certificate is validated against keyring, if provided</td>
</tr>
<tr>
<td>Required</td>
<td>Required</td>
<td>Certificate is validated against keyring</td>
</tr>
<tr>
<td>SAFCheck</td>
<td>Required</td>
<td>Certificate is validated against keyring and must be associated with a user ID in the security product</td>
</tr>
</tbody>
</table>

If the certificate fails validation, the secure connection does not initialize successfully. The default setting for ClientAuthType is Required. For applications that do not issue AT-TLS ioctl calls to obtain the certificate or user ID of the client, the Required setting ensures that any client that connects provides a valid client certificate. The ClientAuthType setting of PassThru should be used only for applications that will get the certificate from AT-TLS using the SIOCTTLSCTL ioctl call and implement their own security methods to validate the certificate. The ClientAuthType setting of Full can be used for applications that want to validate the client certificate if provided, but do not require a client certificate to establish a secure connection. The ClientAuthType setting of SAFCheck provides an additional level of security when using client authentication by requiring AT-TLS to derive a user ID associated with the certificate. An application can then get the user ID from AT-TLS using the SIOCTTLSCTL ioctl after the secure connection has been established. The user ID can be used to either verify the user ID presented by the client during the application’s protocol flows or eliminate the need for a user ID to be sent by the client.

**Specifying the key ring**

AT-TLS configuration can be simplified by using key rings with a common name stored in RACF. The SAF key ring name is specified as userid/keyring. The current user ID is used if only the key ring name is specified. A value that begins with a forward slash is interpreted as the path name of a gskkyman key ring. A PKCS #11 token name is specified as *TOKEN*/token-name. *TOKEN* indicates that the specified key ring is actually a token name.

**Configuring more sophisticated security**

This topic describes decisions you can make to achieve more elaborate levels of security.

---

Application Transparent Transport Layer Security data protection 1105
Protocol versions

TLSv1, TLSv1.1, and TLSv1.2 provide stronger security than SSLv2 or SSLv3. By default, SSLv2 and SSLv3 are not supported in AT-TLS policy. To use older applications that do not support the newer protocols, set SSLv2 or SSLv3 on.

Cipher suite specification

The set of SSL protocol cipher specifications to be allowed for the secure session can be set. You should not include any that you do not want to allow. Order is important. System SSL selects ciphers according to the server’s order of usage preference. The first cipher in the server’s list that is also in the client’s list is selected. Other implementations might work differently.

AT-TLS does not pass any cipher suites to System SSL by default. For the list of cipher suites supported and the default order used if none is specified, see z/OS Cryptographic Services System SSL Programming.

Guideline: Code TTLSCipherParms statements to support newer cipher algorithms, such as elliptical curve cipher suites, AES Galois Counter Mode (GCM) cipher suites, or cipher suites that use SHA2-based digests.

Requirement: Integrated Cryptographic Service Facility (ICSF) must be active for elliptic curve ciphers and for ciphers using AES-GCM.

If the CSFSERV class is defined, the user ID that is associated with the AT-TLS application must have READ access to the following resources in that class:

- CSF1DVK
- CSF1GAV
- CSF1GKP
- CSF1PKS
- CSF1PKV
- CSF1SKD
- CSF1SKE
- CSF1TRC
- CSF1TRD

For more information about elliptic curve cryptography support, see z/OS Cryptographic Services System SSL Programming.

Certificate validation

You can specify that certificates should be validated by using the following methods:

- Only the method described in RFC 2459
- Only the method described in RFC 3280
- Only the method described in RFC 5280
- Any of the methods that are described in RFC2459, RFC3280 and RFC5280

FIPS 140-2 support

You can configure AT-TLS to support FIPS 140-2. Specify either On, Level1, Level2, or Level3 for the FIPS140 statement of the TTLSGroupAction statement.

For information about configuring System SSL to run in FIPS 140-2 mode, see the System SSL and FIPS 140-2 topic in z/OS Cryptographic Services System SSL Programming.

Requirement: ICSF must be active before starting AT-TLS groups configured to support FIPS140. For information about configuring ICSF to support FIPS 140-2, see the topic about operating in compliance with FIPS 140-2 in z/OS Cryptographic Services ICSF Writing PKCS #11 Applications.
If the RACF CSFSERV class is defined, the user ID associated with the TCP/IP stack and any application user ID that is using the TTLSGroup must be given READ access to the CSFRNG resource within the CSFSERV class. If the CSFSERV class is defined and Diffie-Hellman is being used, the application user ID must be given READ access to the CSF1TRC, CSF1DVK, CSF1GKP, CSF1GSK, CSF1GAV, and CSF1TRD resources within the CSFSERV class.

Certificate revocation support

Applications requiring validation of the partner’s certificate can optionally check to see if the certificate has been revoked. Certificate revocation checking can be done using a certificate revocation list (CRL) obtained from a LDAP or HTTP server or by using the certificate revocation status obtained from an OCSP responder. You can configure any combination of certificate revocation by using the following AT-TLS policy statements:

- TTLSGskHttpCdpParms
- TTLSGskLdapParms
- TTLSGskOcspParms

Guideline: Connections that are used by System SSL to contact the CRL service should not fall under an enabled AT-TLS policy because these connections can be made before AT-TLS policy is installed.

Encryption key refresh

The SSLv3, TLSv1, TLSv1.1, and TLSv1.2 protocols allow the encryption key to be renegotiated during a secure connection. Renegotiating the encryption key can provide a higher level of security for long-running connections. The AT-TLS default is to not reset the cipher.

To enable AT-TLS to request a reset of the cipher, you can specify a time interval in the range 1–1440 seconds using the ResetCipherTimer statement. The cipher reset is requested when the timer expires and the next application read or write is completed. The time interval is restarted when the cipher has been changed. Both ends of the secure connection must agree to perform another handshake to renegotiate the cipher. By default, both the client and server must support RFC 5746 renegotiation. The HandshakeRole Client end must initiate this handshake. The HandshakeRole Server end can send an alert to the client requesting another handshake. The client is free to ignore or postpone the request. The server is free to refuse a handshake request sent by the client for another handshake.

Additional security customization considerations

This topic provides additional information that you might want to use to customize security for your environment.

Handshake timer

Certain configuration or application protocol mismatches can lead to stalled connections. The TLS handshake protocol always expects the end of the connection configured as HandshakeRole Client to send the first message. One connection stall scenario results when both ends of the connection are configured as HandshakeRole Server and wait for a ClientHello record from the other end. Another connection stall scenario results when the end of the connection that normally sends the first application data is configured as HandshakeRole Server, but the partner application is not configured to use a secure connection. The HandshakeRole Server end is waiting for a ClientHello, and the nonsecure end is waiting for application data.

You can use the HandshakeTimer action parameter to control the time that AT-TLS should wait during TLS handshake negotiation before resetting the connection. AT-TLS times two different handshake intervals, handshake start and handshake completion. The handshake start interval is intended to detect configuration problems that result in neither partner sending data. The handshake completion interval is intended to detect problems that might stall a handshake in one of the TLS protocol implementations.
The handshake start interval begins when AT-TLS is ready to begin a TLS handshake, and ends when the hello handshake record is received from the partner. On the initiating or active side of the connection, the handshake start interval used is five times the specified HandshakeTimer value, because it includes:

- The network time for the ClientHello record to reach the partner if HandshakeRole is Client.
- The time a connection spends on the partner’s listen backlog.
- The time before the partner causes the connection to be mapped.
- The time spent on the partner AT-TLS work queue.
- The time spent by the partner initializing a new System SSL environment, if necessary.
- The network time for the partner's ServerHello or ClientHello record to be returned.

On the listening or passive side of the connection, the handshake start interval used is the specified HandshakeTimer value, because it includes only the network time for one or both hello records.

Handshake start interval timeouts result in AT-TLS return code 5004 and a connection reset.

The handshake completion interval begins when the hello handshake record is received from the partner, and ends when the System SSL gsk_secure_connection_init() service returns to AT-TLS. The handshake completion interval used is the specified HandshakeTimer value on either active or passive connections.

Handshake completion interval timeouts result in AT-TLS return code 5005 and a connection reset.

The HandshakeTimer action parameter has a default value of 10 seconds. If you determine that you are getting handshake time-outs that are caused by network delays or application workload rather than configuration or application errors, you should increase the value. On the other hand, if you determine that handshakes normally complete much faster in your environment and you would like to detect the occasional incorrectly configured partner more quickly, you can decrease the value.

**Diagnostic traces**

In addition to the steps for diagnosing AT-TLS problems described in z/OS Communications Server: IP Diagnosis Guide, you might need to collect a System SSL trace when you are diagnosing an AT-TLS problem. The only method for collecting this trace is by using GSKSRVR CTRACE, as described in z/OS Cryptographic Services System SSL Programming. You cannot use the GSK_TRACE environment variable because it causes an abend if it is used with AT-TLS. When you use GSKSRVR CTRACE to diagnose AT-TLS problems, the job name that you specify on the JOBNAME parameter of the CTRACE command should be the TCP/IP job name rather than the application job name.

If you are not using any other features provided by the GSKSRVR started task, then you can use the sample procedure provided in the SGSKSAMP library without any changes.

**Diagnosis considerations**

Applications that implement SSL or TLS can control whether non-encrypted application data is included in diagnostic traces. Lower layers have access to only encrypted data. When using AT-TLS, the TCP, PFS, and SOCKAPI layers have access to non-encrypted data. The AT-TLS default is to suppress this data in CTRACE records generated by these layers to protect the application's users. If you need to see this data in these records to diagnose a problem, you can set CtraceClearText ON.

AT-TLS writes messages to syslogd using the jobname of the TCP/IP started task. The AT-TLS default behavior is to write syslogd messages to the daemon facility. Other TCP/IP functions, such as the SNMP TCP/IP subagent, also use the job name of the TCP/IP started task and specify the daemon facility name when writing records to syslogd. Because the job name and syslog facility name of the AT-TLS records and the TCP/IP function records are the same, filters cannot be used to direct the AT-TLS records to a different output file. If you want AT-TLS records to go to a different output file, configure SyslogFacility Auth on the TTLSGroupAdvancedParms statement to direct the messages from that group to the Auth facility. The job name will remain the job name of the TCP/IP started task. You can then set up filtering based on the job name of the TCP/IP started task and the auth facility in the syslogd configuration file to direct AT-TLS records to a different output file.

The Trace value is interpreted by AT-TLS as a bit map. Each of the options is assigned a value that is a power of 2. You should add together the values of each option that you want to activate.
The default Trace value is 2, which provides error messages to syslogd. While you are deploying a new policy, you might find it beneficial to specify a Trace value of 6 or 7. This provides connection info messages, in addition to error messages in syslogd. The info messages provide positive feedback that connections are mapping to the intended policy.

Trace options event (8), flow (16), and data (32) are intended primarily for diagnosing problems. Trace values larger than 7 can cause a large number of trace records to be dropped instead of being sent to syslogd.

**Tip:** Use a TTLSConnectionAction with a higher Trace value to diagnose problems in a production environment. You can temporarily define a high priority TTLSRule with conditions that cover only a small number of problem connections. This temporary rule can reference the same TTLSGroupAction and TTLSEnvironmentAction that your production rule references, and a TTLSConnectionAction with the Trace level you want for diagnosis.

**TLS function negotiation**

TLS protocols enable the TLS client and TLS server to negotiate additional functionality for a connection. If either the TLS client or TLS server does not understand a function, the function is not used on the connection. However, the TLS client or TLS server might require that the function be supported by the remote partner. If the remote partner does not support the function, the connection can be closed. Each function can be configured as Required, Optional, or Off.

- **Required**
  The connection ends if the remote endpoint does not accept the TLS function.

- **Optional**
  The function is negotiated on the connection, but the connection does not end if the remote partner does not support the function.

- **Off**
  The function is not supported on the connection. If the remote partner requires this function, the remote partner closes this connection.

**Guideline:** For TLS servers, configure the functions as Optional to prevent remote partners that require this extension from being unable to connect.

**Wireless performance**

AT-TLS supports the following negotiated functions:

- **Maximum SSL fragment length**
  This TLS function negotiates the maximum size of unencrypted data that can be sent in a single SSL fragment. Without this function, 16 K is the maximum fragment length. A TLS client can negotiate a size of 512, 1 K, 2 K or 4 K. Some clients need to use the smaller size because of memory or bandwidth limitations.

- **Truncated HMAC**
  TLS cipher suites use the MAC construction HMAC with either MD5 or SHA-1 (RFC 2104) to authenticate record layer communications. The truncated HMAC function saves bandwidth by truncating the HMAC to 80 bits.

**Certificate selection**

When AT-TLS supports a server, the certificate designated as the default for the key ring is used. Use the CertificateLabel parameter to explicitly identify a different certificate that you want to use.

If the SSL server needs to support multiple host names and multiple certificates, you can use the Server Name Indication function. The Server Name Indication function enables you to define pairs of certificate labels and host names. Use the HandshakeServerCertLabel parameter to specify these pairs.
The SSL client must support the Server Name Indication function as well. The SSL client includes a host name during the SSL handshake, which allows the matching certificate to be used.

When AT-TLS supports a client, you can use the HandshakeServerName parameter to specify the host name to be included in the SSL handshake.

For more information on configuring the HandshakeServerNameInd function, see “TLS function negotiation” on page 1109.

Session caching

SSL can cache session information based on the Session ID (SID). SSL connections can request that a previous session be resumed. When session information is found in the cache, connections can use the SSL short handshake, which requires less processing. The number of SIDs cached, the length of time that a SID is held in the cache, and whether the cache is available across the sysplex can be configured using the TTLSGskAdvancedParms statement.

AT-TLS access control considerations

Access to key rings and certificates is verified by System SSL when SSL environments are initialized. Access to certificate private keys is verified by ICSF when asymmetric encryption services are requested that require the private keys. AT-TLS invokes System SSL services that cause these access control checks to occur on tasks created in the TCP/IP address space. TCP/IP replicates the security environment of the user running the application that owns the socket at the time AT-TLS policy is mapped, before invoking these System SSL services.

Several common application models were considered to determine the most appropriate time for replicating the security environment. Replication occurs when AT-TLS policy is mapped. Policy mapping occurs during processing of the first occurrence of connect, a SIOCTTLSCTL IOCTL, select for socket readable or writable, poll for socket readable or writable, or call that sends or receives data over the socket. This defers security environment replication for applications such as INETD until after the accept(), fork(), setuid(), and exec() sequence of services has established the server application process.

In the CICS socket environment, transaction security environments are not visible to AT-TLS support. The CICS job and all of its transactions appear to the stack as a single server application with a single z/OS UNIX process ID running in the security environment of the CICS job. All AT-TLS policy lookups, System SSL key ring authorization checks, and ICSF private key authorization checks are processed using the identity of the CICS job. Connections established, whether active or passive, can perform TLS handshake processing as either the client or server. All of the connections established by a single CICS job are able to share the session ID cache in the SSL environment. The CICS job should use a private key ring with a server certificate. The key ring used must contain the chain of root certificates needed to validate the server certificate it presents to the client. If the server requires client authentication, it must also have any other root certificates necessary to validate client certificates presented on its key ring.

Application model considerations

AT-TLS support provides for several typical socket application models. Socket applications with significantly different models might not benefit from AT-TLS.

Client application model

As shown in Figure 134 on page 1111, this type of application runs entirely within the security environment of a single user. Many users might use the application, but each usage is independent, runs in a separate process, and should not share System SSL information with other processes. All socket calls for each usage of the application are made from the same z/OS UNIX process. Most connections are active connections initiated with the connect() service by this application to a server. Some client applications, such as web browsers, repeatedly connect to servers at the same or different IP addresses.
Some client applications, such as FTP or REXEC, support a second parallel connection with the server. This is often a passive connection, established by binding to an ephemeral port and listening for a single connection back from the server's IP address. For a description of an alternative method of mapping policy for these special cases, see “Secondary connection application model” on page 1115.

Figure 134. Client application model

All connections established by this application, whether active or passive, perform TLS handshake processing as a client. All of the connections established by a single process under the same user ID should be able to share the session ID cache in the SSL environment. If the server does not require client authentication, this client can use a shared key ring containing only the root certificates needed to validate the server’s certificate. If the server does require client authentication, each user ID needs to own a key ring that contains that user's certificate, in addition to the necessary root certificates. RACF key ring names are qualified with the owning user ID and are specified as userid/keyring. If the user ID is not explicitly specified on the AT-TLS key ring parameter, the current user ID is used. Therefore, key ring names can be the same across different user IDs. If the same key ring name is used by all client user IDs, a single TTLSEnvironmentAction keyring parameter can represent all clients required to support client authentication. AT-TLS policy administration is simplified if the individual key rings all have the same key ring name.

Server application model

As shown in Figure 135 on page 1112, this type of application runs entirely within a single z/OS UNIX process. Connections can be either passive connections returned from a listening socket by the accept() service, or active connections initiated with the connect() service. Communication partners can be client applications or peer servers. Connections can be processed by subtasks or pthreads within the server process. The initial read or write of data on the connection is done under the primary security environment of the server process. Some server applications allow a client to log in with a user ID on the server system and can place this client-specified identity on the subtask or pthread used to access resources on behalf of the client. The user ID associated with the server is used for AT-TLS purposes, regardless of this ability to change to the client-specified identity.
Connections established by this application, whether active or passive, can perform TLS handshake processing as either a client or server. All of the connections established by a single process, under the same user ID and performing the handshake as a client or as a server, should be able to share a session ID cache in the SSL environment. The server process should use a private key ring with a server certificate. The key ring used must contain the chain of root certificates needed to validate the server certificate it presents to the client. If the server requires client authentication, it must also have any other root certificates necessary to validate the client certificates presented on its key ring.

**Forked server application model**

As shown in Figure 136 on page 1113, this type of application is forked by a daemon application, such as INETD, to handle a single passive connection to a socket that the daemon is listening on. The daemon invokes the bind(), listen(), and accept() services on the parent socket. It then forks a new process to handle each child connection, optionally changes the new process to a different identity, and optionally execs a configured server application. The server application reads and writes data on the child connection.

Some server applications support a second parallel connection with the client. This is often an active connection, established by connecting back to an ephemeral port opened by the client at the client's IP address. For a description of an alternative method of mapping policy for these special cases, see “Secondary connection application model” on page 1115.
Many server applications allow the client to log in with a user ID on the server system. Some server applications change the security environment of the server process to the client-specified identity prior to accessing resources on behalf of the client. Other server applications set up another communications path (pseudo terminal, named pipe, UNIX domain socket, and so on) and then fork an additional client process. The server changes the security environment in this client process to the client-specified identity, and then execs a client-specified program or login shell.

The initial child connection transferred by the daemon to the server process, and any additional connections established by the server process, perform TLS handshaking as the server, optionally requiring client authentication. Each forked server process runs under the same user ID. All of the server processes forked to handle child connections of the same parent connection should be able to share the session ID cache in the SSL environment. The server processes can use a shared key ring with a site certificate or a private key ring with a server certificate. The key ring used must contain the chain of root certificates needed to validate the site or server certificate it presents to the client. If the server requires client authentication, it must also have any other root certificates necessary to validate client certificates presented on its key ring.

Any client process forked by the server process is treated as a new application by AT-TLS. New connections established will not share an SSL environment with the server process that created them.

**CICS transaction model**

TCP/IP CICS socket support provides a CICS resource manager that invokes z/OS UNIX socket services. It also provides a CICS Listener transaction that accepts passive connections from a listening socket. Each listening socket has a configured transaction that is launched to process a single established connection.

For more information on configuring TCP/IP CICS socket support, see z/OS Communications Server: IP CICS Sockets Guide.
Advanced application considerations

Some applications need to be aware of when a secure connection is being used or examine the certificate presented by the partner. Other applications need to control if and when the TLS handshake occurs. These applications typically support both TLS and non-TLS connections over the same port. They define an application protocol for negotiating whether to use TLS and when to begin. In both cases, these applications need to be aware that TLS is being used on the connection. However, you might not want to, or might not be able to, use any SSL toolkits in the application. AT-TLS support provides the SIOCTTLSCTL ioctl commands that can be used in these situations.

Some applications establish a second connection using ephemeral ports or after the server has changed to a client supplied identity. These secondary connections need to be associated with the policy and security environment used on the primary connection. AT-TLS provides special support for these applications.

AT-TLS aware application considerations

Applications that need to examine the partner's certificate can issue the SIOCTTLSCTL IOCTL with request type TTLS_RETURN_CERTIFICATE to get the certificate at any time during a secure connection. Applications that are running under a policy with the HandshakeRole parameter set to CLIENT receive the server's certificate. Applications that are running under a policy with the HandshakeRole parameter set to ServerWithClientAuth receive the client's certificate if provided.

Applications configured as HandshakeRole ServerWithClientAuth that need to examine or use the user ID associated with the certificate in SAF can issue the SIOCTTLSCTL ioctl with request type TTLS_QUERY_ONLY or TTLS_RETURN_CERTIFICATE. If a partner certificate is available on the secure connection, AT-TLS uses a RACF service to extract the associated user ID. If no client certificate is available, or no user ID has been associated, the ioctl returns zero as the associated user ID length.

AT-TLS controlling application considerations

Applications that need to control AT-TLS behavior, using the SIOCTTLSCTL IOCTL with the TTLS_INIT_CONNECTION, TTLS_RESET_SESSION, or TTLS_RESET_CIPHER request flags, must have the ApplicationControlled parameter set to ON in their TTLEnvironmentAdvancedParms or TTLSConnectionAdvancedParms statement. This causes AT-TLS to postpone the TLS handshake. After the connection is established, the application can issue the SIOCTTLSCTL IOCTL to get the current AT-TLS connection status and determine whether or not AT-TLS support is available on this connection. When the application is ready for AT-TLS to perform the TLS handshake, it issues the SIOCTTLSCTL IOCTL with request type TTLS_INIT_CONNECTION. The SIOCTTLSCTL IOCTL initiates an AT-TLS policy lookup, if one has not yet been done, and assigns a rule and actions to the connection if a match is found. For more IOCTL information, see z/OS Communications Server: IP Programmer’s Guide and Reference.

Some application protocols provide a way for the client and server programs to negotiate whether to use the TLS or SSL protocol to protect data on the connection. This cleartext negotiation typically occurs very early in the connection. When both partners agree to use TLS, they initiate the handshake. These applications can take advantage of AT-TLS. The policy must indicate ApplicationControlled ON. After the connection is established, the application can use the SIOCTTLSCTL IOCTL to determine whether AT-TLS support is configured, policy covers the connection, and the policy specifies ApplicationControlled ON. The application can then send and receive cleartext data to negotiate the use of TLS. When both partners agree, they each must initiate a secure connection. The AT-TLS application can use the SIOCTTLSCTL ioctl with TTLS_INIT_CONNECTION to initialize the secure connection. AT-TLS performs the initial handshake and provides encryption and decryption services for the application. The application can simply send and receive cleartext over the socket as it would if it were not a secure connection.

The application can also use the SIOCTTLSCTL IOCTL to reset the cipher or the session. Resetting the cipher causes AT-TLS to initiate another handshake. If the session is reset first, the subsequent handshake is a full handshake. If the session has not been reset, a short handshake is attempted for the subsequent handshake. The partner application must agree to the short handshake.
Secondary connection application model

Some applications create two connections between the client and server programs. These applications typically have a single primary connection that is bound to a well-known port on the server side. After exchanging some information, a second connection is established. This second connection often uses dynamically assigned ports on both ends. Examples of this behavior include the stderr connection in the rsh, rexec, and rlogin family of applications, as well as the firewall-friendly FTP data connection. It is often not possible to define a set of policy rule conditions to correctly map these secondary connections on the client side or when the server forks a new process, with a dynamic job name, for each connected client.

In other cases, this second connection is established after the server has changed to a client-supplied identity. Mapping this second connection to AT-TLS policy as a new and independent connection would force the use of a different System SSL environment. The client-supplied identity would need to have access to the certificate private keys. Normal FTP data connections are an example of this behavior.

AT-TLS provides an alternate method of mapping policy for these secondary connections. This alternate method causes the secondary connection to share the System SSL environment and security environment of the associated primary connection.

To activate the alternate policy mapping method, define a policy rule using conditions that will map the primary connection. In this policy, specify the SecondaryMap parameter with a value of ON. When this policy is mapped to a primary connection, an entry is made in an internal table. Future connections do a normal policy lookup, and then look in the internal table for an entry with the same process ID and pair of IP addresses. If a matching entry is found and the new connection has no mapped policy, or has a mapped policy with a lower priority than the matching entry, the new connection is marked as a secondary connection and uses the same policy and user ID as the primary connection.

You should use this alternate policy mapping method only for client applications and server applications that have a single primary connection. Careful consideration should be given before using it for non-forking server applications that accept multiple primary connections, such as MVRSHD (TCP/IP's combined rsh and rexec server for the TSO environment). The alternative method of policy mapping always associates secondary connections with the most recent primary connection mapped by this process. When the process establishes multiple primary connections, the alternate mapping method is not able to reliably associate secondary connections with the correct primary connection. You should not use this alternate policy mapping method when the primary connections can map to different policies based on client IP address or multiple server listening port numbers. You should use normal policy mapping with a job name condition for the secondary connections of non-forking servers.
The z/OS Load Balancing Advisor communicates with external load balancers and one or more Load Balancing Agents. The main function of the Load Balancing Advisor is to provide external TCP/IP load balancing solutions, such as the Cisco Content Switching Module (CSM), with recommendations on which TCP/IP applications and target z/OS systems within a z/OS sysplex are best equipped to handle new TCP/IP workload requests. These recommendations can then be used by the load balancer to determine how to route new requests to the target applications and systems (that is, how many requests should be routed to each target). The recommendations provided by the Advisor are dynamic, and can change as the conditions of the target systems and applications change. The recommendations include several key components:

- **State of the target application and system**
  This includes an indication of whether the target application and target system is active. This enables the load balancer to exclude systems that are not active or do not have the wanted application running.

- **z/OS Workload Management (WLM) system-wide recommendations**
  WLM recommendations provide a relative measure of a target system's ability to handle new workload, as compared to other target systems in the sysplex. The WLM recommendations are derived using several measures, including each system's available general CPU capacity, which is used for both system members and application members. For application members, the amount of available System z Application Assist Processor (zAAP) capacity and System z Integrated Information Processor (zIIP) capacity can also be considered.

  If systems are 100% used, a WLM recommendation is a measurement of available displaceable capacity (capacity that can be displaced by higher importance workloads). The latter is important for scenarios where systems might be 100% used, but some might be running a larger portion of lower importance work (as defined by the WLM policy) that can therefore be displaced by higher importance workloads.

- **z/OS WLM server-specific recommendations**
  These recommendations are similar to the WLM system-wide recommendations, but are more specific as they are based on the following factors:
  - How individual server applications are doing compared to the WLM policy goals that are specified for that workload.
  - The amount of displaceable capacity of the general, zAAP, and zIIP processor work on each system, which is based on the following factors:
    - The workload's importance (as defined by the WLM policy).
    - The proportion of each processor type that is being consumed by the application's workload.

  These recommendations can help the load balancers avoid selecting application servers that are experiencing performance problems (that is, not meeting the specified WLM policy goals).

- **Application server health from a TCP/IP perspective**
  TCP/IP statistics for target applications are monitored to determine whether specific server applications are encountering problems keeping up with the current workload. For example, is a target TCP server application keeping up with TCP connection requests? Or are requests being rejected because the backlog queue is full? In scenarios where this occurs, the recommendations passed back to the load balancers are adjusted appropriately, so that the load balancer can direct fewer connections to any application that is experiencing these problems. These recommendations are provided for both UDP and TCP server applications. These recommendations are referred to as Communication Server weights in this information.

Figure 137 on page 1118 illustrates the relationship between the load balancer, a z/OS Load Balancing Advisor, and Load Balancing Agents.
Figure 137. z/OS Load Balancing Advisor

The load balancer is configured with a list of systems and applications that it will balance. The load balancer tells the Load Balancing Advisor about the applications by specifying an IP address, port, and protocol, or about the systems by specifying an IP address. The Advisor is configured with a poll interval at which the Agents update the Advisor’s data. You can configure the Advisor with a list of authorized load balancers and a list of authorized Load Balancing Agents with which it can gather data, or you can use AT-TLS support to provide the authorization for the load balancers and Load Balancing Agents. Each Agent gathers data on its own z/OS system about the TCP/IP stacks and applications running on that system.

The Agent is configured with the information it needs to contact the Advisor. The Advisor consolidates the data from all its Agents, and returns the data to the load balancer to advise the load balancer about the status of the systems and applications.

Before using the z/OS Load Balancing Advisor, you need to consider the characteristics of your environment, such as whether you need to use TLS/SSL (using AT-TLS on z/OS), what TCP/IP workloads you want to load balance, what load balancing solution you will use, and so on, as described in "Steps for preparing to use the z/OS Load Balancing Advisor" on page 1118.

Steps for preparing to use the z/OS Load Balancing Advisor

This topic describes the preparation needed to use the z/OS Load Balancing Advisor, such as selecting a load balancing solution and considering who has authority to start the Advisor and Agents.

Before you begin
You must meet the following requirements:

- You must have at least one external load balancer that supports the Server/Application State Protocol (SASP). This load balancer must have IP connectivity to each z/OS system in the sysplex that is to participate in load balancing. If you are using TLS/SSL (through AT-TLS on z/OS) for incoming connections to the Load Balancing Advisor, the load balancer must also be capable of using TLS/SSL on its SASP communication flows.
Read Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1093 and Chapter 14, “Policy-based networking,” on page 761 to decide how you want the Advisor and Agents to use AT-TLS policies. To use AT-TLS, AT-TLS must be enabled and the Policy Agent must be configured and activated for each TCP/IP stack where the Load Balancing Advisors and Load Balancing Agents might run.

**Procedure**

Perform the following steps to prepare to use the z/OS Load Balancing Advisor:

1. Consider whether you need to use TLS/SSL (using AT-TLS on z/OS).
   
   See “Step 1: Consider whether to use TLS/SSL (using AT-TLS on z/OS)” on page 1119.

2. Evaluate TCP/IP workloads to be load balanced and select a load balancing solution. (optional)
   
   See “Step 2: Evaluate TCP/IP workloads to be load balanced and select a load balancing solution (optional)” on page 1120.

3. Decide who will have authority to start the Advisor. (optional)
   
   See “Step 3: Decide who will have authority to start the Advisor (optional)” on page 1120.

4. Decide who will have authority to start the Agents. (optional)
   
   See “Step 4: Decide who will have authority to start the Agents (optional)” on page 1121.

5. Authorize the Agents to use WLM services.
   
   See “Step 5: Authorize the Agents to use WLM services” on page 1121.

6. Determine how the Advisor and agent are to interact in a subplexing environment (optional)
   
   See “Step 6: Determine how the Advisor and agent are to interact in a subplexing environment (optional)” on page 1122.

**Step 1: Consider whether to use TLS/SSL (using AT-TLS on z/OS)**

As you plan to use the z/OS Load Balancing Advisor, consider whether you need to use TLS/SSL (using AT-TLS on z/OS). The z/OS Load Balancing Advisor acts as a TCP server application, listening on two distinct ports that allow both Load Balancing Agents and external load balancers [or automated domain name registration (ADNR)] to connect to it. You need to restrict the ability to establish a connection to either of these ports, because sensitive interfaces can be exploited after a connection is accepted by the Load Balancing Advisor. For the agent listening port, you need to ensure that only authorized agents are allowed to connect, because these agents are responsible for providing sensitive information that indicates server application availability, health, and performance. For the external load balancer Server/Application State Protocol (SASP) port, you need to ensure that only authorized load balancers and ADNR are allowed to connect, because this interface can be used to obtain sensitive information regarding TCP/IP applications in a sysplex, CPU usage information for each system, and so on. You can use AT-TLS to encrypt data between the external load balancer and the Advisor's TCP/IP stack, and between the Agent's TCP/IP stack and the Advisor's TCP/IP stack.

You can use one or both of the following methods to authorize connections to the z/OS Load Balancing Advisor:

- You can explicitly configure the following lists:
  - The list of IP addresses of all the external load balancers (including ADNR) that are allowed to connect to the Load Balancing Advisor
  - The list of source IP addresses and source ports that each of the Load Balancing Agents use to connect to the Load Balancing Advisor
- You can establish policies using the z/OS Policy Agent so that the Agents, ADNR, or both are required to use TLS/SSL through AT-TLS, and load balancers are required to use TLS/SSL.

Although the configuration parameters might be sufficient in certain environments in which the Load Balancing Advisor, Agents, and external load balancers all are inside a secure network (that is, isolated by a firewall and so on), they might not be sufficient in environments in which the network is not considered to be as secure or in which the need to protect against IP address spoofing attacks is important.
With AT-TLS, the z/OS Load Balancing Advisor provides you with a more secure way to authorize access to critical Load Balancing Advisor resources using industry-standard network security standards like TLS/SSL. The AT-TLS approach also provides some additional benefits:

- **Ease of use**
  - Reduces the number of IP address and port lists that need to be maintained in the Load Balancing Advisor and coordinated with the external load balancers and Load Balancing Agents.
  - Eliminates the need for defining a source IP address and port for each Load Balancing Agent. This includes the Agent configuration file, the TCP ports that need to be reserved in the TCP/IP profile, and the DVIPAs that are recommended for the source IP address that is used for Agent connections.

- **Outage avoidance**
  If you do not use AT-TLS, adding an Agent instance into the sysplex requires updates to the Load Balancing Advisor configuration, which in turn requires a recycle of the Load Balancing Advisor so that it can process the configuration changes. With AT-TLS, you can add an Agent instance into the sysplex without recycling the Advisor.

For more information about using AT-TLS, see Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1093.

**Step 2: Evaluate TCP/IP workloads to be load balanced and select a load balancing solution (optional)**

The first steps involve identifying the TCP/IP applications that you want to load balance, the systems that these applications will be running on, and ensuring that these applications can exploit load balancing. When this is done, evaluate the load balancing techniques that best meet your requirements. You might want to use a combination of workload balancing solutions.

There are various technology choices for performing IP load balancing in a sysplex environment. For a discussion of some of these choices, see “Workload balancing” on page 449.

**Step 3: Decide who will have authority to start the Advisor (optional)**

Explicit authority should be granted to all users that can start the Advisor, to prevent unauthorized users from starting it. If you do not grant explicit authority, any user able to issue the START command can start the Advisor.

**Tip:** You might want to combine this step with the next two steps, “Step 4: Decide who will have authority to start the Agents (optional)” on page 1121, and “Step 5: Authorize the Agents to use WLM services” on page 1121, because these steps use similar commands.

**Steps for granting authority to start the Advisor**
Follow these steps after you decide who you want to be able to start the Advisor.

**Procedure**
Perform the following steps to grant authority to start the Advisor:

1. Ensure that the OPERCMDS class is active and RACLISTed, and RACLIST processing is enabled:

   ```
   SETROPTS CLASSACT(OPERCMDS)
   SETROPTS RACLIST (OPERCMDS)
   ```

2. Define the following OPERCMDS class profile using a security product like RACF:

   ```
   RDEFINE OPERCMDS (MVS.SERVMGR.LBADV) UACC(NONE)
   ```

3. Grant the Advisor access to the OPERCMDS class:

   ```
   PERMIT MVS.SERVMGR.LBADV CLASS(OPERCMDS) ACCESS(CONTROL) -
   ID(userid)
   ```
4. Refresh the OPERCMDS class:

   
   ```
   SETROPTS RACLIST(OPERCMDS) REFRESH
   ```

5. See the EZARACF sample in SEZAINST for specific instructions. All commands that you can issue against the Advisor are MODIFY commands, with the exception of the STOP command used to stop the Advisor. Therefore, you might also want to limit which users are able to issue MODIFY and STOP commands.

**Step 4: Decide who will have authority to start the Agents (optional)**

Explicit authority should be granted to all users that can start the Agents, to prevent unauthorized users from starting them. If you do not grant explicit authority, any user able to issue the START command can start the Agents.

**Steps for granting authority to start the Agents**

Follow these steps after you decide who you want to be able to start the Agents.

**Procedure**

Perform the following steps to grant authority to start the Agents:

1. Ensure that the OPERCMDS class is active and RACLISTERed, and RACLIST processing is enabled.
   
   If you have already done this for the Advisor, you can skip this step.

   ```
   SETROPTS CLASSACT(OPERCMDS)
   SETROPTS RACLIST (OPERCMDS)
   ```

2. Define the following OPERCMDS class profile using a security product like RACF:

   ```
   RDEFINE OPERCMDS (MVS.SERVMGR.LBAGENT) UACC(NONE)
   ```

3. Grant the Agents access to the OPERCMDS class:

   ```
   PERMIT MVS.SERVMGR.LBAGENT CLASS(OPERCMDS) ACCESS(CONTROL) - ID(userid)
   ```

4. Refresh the OPERCMDS class:

   ```
   SETROPTS RACLIST(OPERCMDS) REFRESH
   ```

5. See the EZARACF sample in SEZAINST for specific instructions. All commands that you can issue against the Agents are MODIFY commands, with the exception of the STOP command used to stop the Agents. Therefore, you might also want to limit which users are able to issue MODIFY and STOP commands.

**Step 5: Authorize the Agents to use WLM services**

You might want or need to define the BPX.WLMSERVER resource profile to your security product and grant the Agents access to it. If you are using RACF and already have the resource profile defined and the FACILITY class is enabled, permit the Agents to the resource profile. If you are using a security product other than RACF that by default denies access to the resource profile, grant the Agents access to the resource profile. If you do not already have the resource profile defined and you are using RACF, consult the documentation of other programs and products that require WLM services and coordinate any potential changes with these programs and products.

**Steps for defining the resource profile with RACF**

You can define the BPX.WLMSERVER resource profile to RACF, and grant the Agents access to it.

**Procedure**

Perform the following steps for RACF if you choose to define the resource profile:
1. Ensure that the FACILITY class is active and RACLISTed, and RACLIST processing is enabled:

   SETROPTS CLASSACT(FACILITY)
   SETROPTS RACLIST (FACILITY)

2. Define the following FACILITY class profile:

   RDEFINE  FACILITY (BPX.WLMSERVER) UACC(NONE)

3. Grant the Agent access to the FACILITY class:

   PERMIT   BPX.WLMSERVER CLASS(FACILITY) ACCESS(READ) -
   ID(userid)

4. Refresh the FACILITY class:

   SETROPTS RACLIST(FACILITY) REFRESH

Results

For more information, see the EZARACF sample in SEZAINST.

Step 6: Determine how the Advisor and agent are to interact in a subplexing environment (optional)

If you are configuring the z/OS Load Balancing Advisor in a subplexing environment, you need to decide how you want the Advisor and Agents to interact:

- You need to determine what set of subplexes will exist in your sysplex, both how many VTAM subplexes and how many TCP/IP subplexes within a VTAM subplex.
- You need to decide which subplexes will need Load Balancing Agents and a Load Balancing Advisor.

For information about subplexing environments, see “Sysplex subplexing” on page 420.

In addition, if you are also using Automated Domain Name Registration (ADNR), see Chapter 22, “Automated domain name registration,” on page 1165 for some additional considerations for configuring ADNR in a subplexing environment.

Steps for configuring the z/OS Load Balancing Advisor

The z/OS Load Balancing Advisor provides external TCP/IP load balancing solutions with recommendations on which TCP/IP applications and target z/OS systems within a z/OS sysplex are best equipped to handle new TCP/IP workload requests.

Before you begin

You need to review “Steps for preparing to use the z/OS Load Balancing Advisor” on page 1118.

Procedure

Perform the following steps to configure the z/OS Load Balancing Advisor and one or more Load Balancing Agents.

1. Configure the Advisor and Agents to automatically restart in case of application or system failure.
   (optional)
   See “Step 1: Configure the Advisor and Agents to automatically restart in case of application or system failure (optional)” on page 1123.

2. Configure and start syslogd.
   See “Step 2: Configure and start syslogd” on page 1125.

3. Configure one Advisor per sysplex.
   See “Step 3: Configure one Advisor per sysplex” on page 1126.
4. Configure one Agent per z/OS system in the sysplex.
   See “Step 4: Configure one Agent per z/OS system in the sysplex” on page 1130.

5. Customize the TCP/IP profiles of the TCP/IP stacks on which the Advisor and Agents are to run.
   (optional)
   See “Step 5: Customize the TCP/IP profiles of the TCP/IP stacks on which the Advisor and Agents are to run (optional)” on page 1133.

6. Customize WLM policies for the Advisor and Agents. (optional)
   See “Step 6: Customize WLM policies for the Advisor and Agents (optional)” on page 1138.

7. Configure the external load balancers.
   See “Step 7: Configure the external load balancers” on page 1138.

Step 1: Configure the Advisor and Agents to automatically restart in case of application or system failure (optional)

Although this step is optional, performing it will provide high availability to your target applications. In the event that an Agent fails, the Advisor would indicate that it has no information for any applications running on that system. As a result, target applications on the failing system would cease to receive new workload requests, in most cases, until the Agent is restarted. Automatically restarting the Agent on the same system would minimize this perceived outage. This can be accomplished using automation software or by defining an automatic restart manager (ARM) policy. For more information on defining ARM policies, see z/OS MVS Setting Up a Sysplex. In a sysplex subplexing environment, this step requires additional actions. For information about the changes to this step, see “Considerations for automatic restart in a subplexing environment” on page 1124.

The Agent registers with ARM using the following values:

```
ELEMTYPE=SYSTCPIP
ELEMNAME=EZBsyscloneLBAGENT
TERMTYPE=ELEMTERM
```

where sysclone is a 1- or 2-character shorthand notation for the name of the MVS system. For example, if the sysclone value is 02, the resulting ELEMNAME value is EZB02LBAGENT. For a complete description of the SYSCONLE static system symbol, see z/OS MVS Initialization and Tuning Reference.

This indicates that if the Agent fails on this system, it should be restarted on this system only.

If the Advisor or its underlying system were to fail, the load balancer might continue to distribute workload requests according to the last set of information received from the Advisor, it might resort to preconfigured weights, or it might even stop distributing new work requests to the cluster. (The behavior depends upon the load balancer implementation; consult the load balancer documentation for details.) Therefore, it is important that the Advisor be restarted as soon as possible when a failure occurs, so that it can begin communicating with the load balancer and workload request distribution can resume normally. This restart capability should cover scenarios where the Advisor itself fails, and where the system that the Advisor is running on fails. The Advisor can run on any system in the sysplex and thus can be restarted on any system in the sysplex, as long as it is configured to use dynamic VIPAs and dynamic routing is in effect. The Advisor registers with ARM using the following values:

```
ELEMTYPE=SYSTCPIP
ELEMNAME=EZBLBADV
TERMTYPE=ALLTERM
```

This indicates that the Advisor should be restarted only on the same system in cases where the Advisor itself fails, and also restarted on a different system if the system fails. Using an ARM policy, you can indicate which systems are eligible for running the Advisor in the case of system failures. You also need to ensure that the specified backup systems have all the necessary configuration in place to enable the Advisor to be restarted there.

Some special considerations exist for scenarios where ARM is used and the TCP/IP stack address space terminates, as the result of a failure or of a planned operation. When the TCP/IP stack becomes unavailable, the Advisor also terminates, as it can no longer establish any TCP/IP communications. An
ARM restart of the Advisor will likely fail, as the TCP/IP protocol stack will not be available when the
restarts occur. You can handle these scenarios in the following ways:

- Planned outages of the TCP/IP stack
  
  Manually start the Advisor on another system, as soon as the Advisor terminates on the system where
  TCP/IP is stopped.

- Unplanned outages of the TCP/IP stack
  
  Ensure that an ARM policy (or other automation) is in place to quickly restart the TCP/IP stack on the
  same system. The Advisor also needs to be quickly restarted on the same system. This can be done by
  using an automation software package, or by using the TCP/IP profile AUTOLOG statement.

The AUTOLOG statement also has some important considerations:

- You should place the Advisor in the AUTOLOG statement list to ensure that it is started when TCP/IP is
  started on that system. However, you should specify the NOAUTOLOG parameter on the PORT
  reservation statements for the Advisor ports in the TCP/IP profile. This prevents TCP/IP from monitoring
  and attempting to restart the Advisor, as that could interfere with your automation logic or the ARM
  policy that you have put in place.

- The AUTOLOG function works best on systems where a single TCP/IP stack is active (INET
  environment). For CINET considerations, see "Considerations for automatic restart in a CINET
  environment" on page 1124.

Guideline: Establish an ARM policy with TCP/IP at a lower level than the Advisor and Agent, so that
TCP/IP is restarted before the Advisor and Agent are restarted. For more information, see z/OS MVS
Setting Up a Sysplex.

Requirement: The Load Balancing Advisor and Agent do not run using a system key. Therefore, if you are
using ARM registration, the started task IDs need to be permitted with UPDATE authority to the
associated IXCARM.SYSTCPIP.EZBLBADV and IXCARM.SYSTCPIP.EZBLBAGENT profiles in the FACILITY
class within the SAF product on your system. To enable the Advisor and Agent to register with ARM, use
the following RACF commands to define the profiles and grant update access to the user IDs that are
assigned to start the Advisor and Agent:

```
RDEFINE FACILITY IXCARM.SYSTCPIP.EZBLBADV UACC(NONE)
RDEFINE FACILITY IXCARM.SYSTCPIP.EZBLBAGENT UACC(NONE)
PERMIT IXCARM.SYSTCPIP.EZBLBADV CLASS(FACILITY) ID(LBADV) ACCESS(UPDATE)
PERMIT IXCARM.SYSTCPIP.EZBLBAGENT CLASS(FACILITY) ID(LBAGENT) ACCESS(UPDATE)
SETROPTS RACLIST(FACILITY) REFRESH
```

Restrictions:

- If using AUTOLOG for the Agent, code the NOAUTOLOG parameter on the PORT reservation statement
  for the Agent port in the TCP/IP profile. This prevents the Agent from automatically being cancelled and
  restarted because the Agent does not listen on the port.

- If the Advisor is using IPv6 for the load balancer connections, or if any Agents are using IPv6 to connect
to the Advisor, movement of the Advisor is limited to IPv6–enabled TCP/IP stacks.

Considerations for automatic restart in a CINET environment

If you are considering using the AUTOLOG statement to restart the Advisor in a CINET environment, and
you placed the Advisor in the AUTOLOG statement list of each TCP/IP stack, each stack attempts to start
the Advisor during initialization. Only the first one will succeed, as only a single instance can be active at
any time within a system or within a sysplex.

Considerations for automatic restart in a subplexing environment

When running the Load Balancing Advisor in a subplexing environment, there is one Load Balancing
Advisor for each subplex that participates in load balancing. The subplex is determined by both the VTAM
and TCP/IP subplex group IDs, which are denoted by vv for VTAM and tt for TCP/IP. These subplex group
IDs are reflected in the TCP/IP sysplex group name, which is of the format EZBTvvt. Each Load Balancing Advisor registers with ARM with the following parameters:

- **ELEMTYPE=SYSTCPIP**
- **ELEMNAME=EZBTvvtLBADV**
- **TERMTYPE=ALLTERM**

You must define an ARM policy. For the EZBTvvtLBADV element name, you must specify the **TARGET_SYSTEM** keyword to indicate the systems on which the Advisor can be restarted. This ensures that the Load Balancing Advisor for a subplex is restarted only on a system that is in the same subplex. That is, it is restarted on a system that has a VTAM that was started with the same XCFGRPID (vv) and that has an available TCP/IP stack with the same XCFGRPID (tt).

In a subplexing environment, there must be one Load Balancing Agent per subplex that participates in load balancing on each z/OS system. Each Load Balancing Agent registers with ARM with the following parameters:

- **ELEMTYPE=SYSTCPIP**
- **ELEMNAME=EZBsysclonevvttLBAGENT**
- **TERMTYPE=ELEMTERM**

where:

- **sysclone** is a 1- or 2-character shorthand notation for the name of the MVS system. For a complete description of the SYSCLONE static system symbol, see z/OS MVS Initialization and Tuning Reference.
- **vvtt** is the last 4 characters of the **sysplex_group_name** parameter in the Agent configuration file. If this parameter is not specified, **vvtt** is omitted.

For example, if the **sysclone** value is 02 and the **sysplex_group_name** is EZBTCPCS, the resulting **ELEMNAME** value is EZB02CPCSLBAGENT.

**Requirement:** When ARM registration is used, the started task IDs for each Agent and each Advisor must be permitted with UPDATE authority to the IXCARM.SYSTCPIP.elemname profiles in the FACILITY class in the SAF-compliant security product on your system. The **elemname** value is the EZBTvvtLBADV value or the EZBsysclonevvttLBAGENT value previously described. You can use the following RACF commands to define the profiles and grant update access to the user IDs that are assigned to the Advisors and Agents.

For each Advisor:

```
RDEFINE FACILITY IXCARM.SYSTCPIP.EZBTvvtLBADV UACC(NONE)
PERMIT IXCARM.SYSTCPIP.EZBTvvtLBADV CLASS(FACILITY) ID(advisor_userid) ACCESS(UPDATE)
SETROPTS CLASSACT(FACILITY)
```

For each Agent:

```
RDEFINE FACILITY IXCARM.SYSTCPIP.EZBsysclonevvttLBAGENT UACC(NONE)
PERMIT IXCARM.SYSTCPIP.EZBsysclonevvttLBAGENT CLASS(FACILITY) ID(agent_userid) ACCESS(UPDATE)
SETROPTS CLASSACT(FACILITY)
```

**Step 2: Configure and start syslogd**

The Advisor and Agent write most log messages and trace data to the syslog daemon (syslogd). A limited number of messages are written to the MVS console, but these are unaffected by syslogd configuration. For the Advisor and Agent to be able to write their log messages and trace data to syslogd, syslogd must be properly configured and started before the Advisor and Agent are started.

Because it is likely that you will be running an Agent on the same system as the Advisor, for better readability, you might want to configure syslogd to place Advisor and Agent log output in separate files. For further information, see “Configuring the syslog daemon” on page 199. In a sysplex subplexing environment, this step requires additional actions. For information about the changes to this step, see “Syslogd considerations in a subplexing environment” on page 1126.

**Tip:** As more data is logged by the Advisor and Agent, performance of the Advisor and Agent can be adversely affected. The amount of data that is logged by the Advisor and Agent is determined by the
debug_level statement. Backing the syslogd output file with a z/OS File System instead of an HFS file system can minimize performance impacts caused by logging.

Syslogd considerations in a subplexing environment

When you are using subplexing, if you will be starting more than one instance of an Advisor or Agent on the same system, you can configure the syslog daemon (syslogd) to place the output from the different instances of the Advisor and Agent into separate files based on job name, or you can use the syslogd -u start option to cause the user ID and job name to be displayed on each line of the syslog. For more information, see “Configuring the syslog daemon” on page 199.

Step 3: Configure one Advisor per sysplex

There can be only one Advisor active in the sysplex at any given time, unless you are using sysplex subplexing. In a sysplex subplexing environment, this step requires additional actions. For information about the changes to this step, see “Configuring Advisors in a subplexing environment” on page 1130.

The Advisor reads configuration data from one file, which might exist as a z/OS UNIX file, a PDS or PDSE member, or a sequential data set. If you plan on allowing the Advisor to move within the sysplex in the case of failure, you probably want the Advisor configuration file or data set to exist on shared DASD, to make it accessible to all systems in the sysplex if necessary. The Advisor configuration file is specified on the CONFIG DD statement in the Advisor start procedure. A sample start procedure is provided in EZBLBADV in SEZAINST.

The Advisor configuration file serves three basic purposes:

• Defines the listening sockets for the load balancers and Agents
• Provides an access control list for specifying which load balancers and Agents can connect to the Advisor
• Customizes some optional parameters

A sample Advisor configuration file is provided in EZBLBADC in SEZAINST.

Define listening sockets/ports (required)

The Advisor maintains at least two, and up to three, listening sockets/ports, one for Agents to connect to and up to two for load balancers to connect to. There are separate IPv4 and IPv6 listening sockets for load balancers. If your TCP/IP stack is not IPv6 enabled, you will not be able to use the IPv6 listening socket.

The Advisor and Agent statements define addresses and ports on the local system and on remote systems. At times, it can be difficult to remember which statements refer to local sockets and which statements refer to remote addresses and ports.

Tip: Any statement containing the word connection refers to a local socket, and any statement containing the word id refers to a remote address and possibly a port.

Specify the local IPv4 address and port that the Advisor listens on for IPv4 load balancer connections with the lb_connection_v4 configuration statement. The default port for communications with load balancers is 3860.

The lb_connection_v6 statement does the equivalent for IPv6 that lb_connection_v4 does for IPv4. You can specify either or both of these statements. For CINET considerations regarding stack termination, see “Configuring one Advisor per sysplex in a CINET environment” on page 1130.

Guideline: To enable movement of the Advisor to another system in the sysplex or to another TCP/IP stack on the same system in the event of failure of the Advisor or its underlying system, use a dynamic VIPA (DVIPA) for the address specified on the lb_connection_v4 and lb_connection_v6 statements. Furthermore, make this DVIPA a unique application-instance DVIPA (defined through VIPARANGE) rather than a multiple application-instance DVIPA (defined through VIPADEFINE), to enable movement of the Advisor if the Advisor itself failed. For CINET considerations with DVIPAs, see “Configuring one Advisor per sysplex in a CINET environment” on page 1130.
Restriction: If the Advisor is using IPv6 for the load balancer connections, or if any Agents are using IPv6 to connect to the Advisor, movement of the Advisor is limited to IPv6–enabled TCP/IP stacks.

Specify the local port that the Advisor listens on for Agent connections with the `agent_connection_port` statement. If the Advisor's TCP/IP stack is IPv6 enabled, the Advisor opens a listening socket for Agents on the IPv6 unspecified address (::) on the port specified by this statement. This enables Agents to connect to the Advisor using either IPv4 or IPv6, and by using any address on the Advisor's system. If the TCP/IP stack is not IPv6 enabled, the Advisor opens a listening socket on the IPv4 unspecified address, 0.0.0.0. This enables Agents to connect to the Advisor using any IPv4 address on the Advisor's system.

Guideline: The port number used on the `agent_connection_port` statement should not be the same as the port used on the `lb_connection_v4` or `lb_connection_v6` statement.

Rules:

- The port number specified on the `agent_connection_port` statement must match the port number specified on the Agents' `advisor_id` statement.
- If at least one IPv4 address is specified in the `lb_id_list` statement, the `lb_connection_v4` statement must be specified. Similarly, if at least one IPv6 address is specified in the `lb_id_list` statement, the `lb_connection_v6` statement must be specified.

Define the access control list

You can use one or both of the following methods for z/OS Load Balancing Advisor security:

- Access control list configuration statements

  The Advisor can control which load balancers and which Agents are allowed to connect to it by maintaining an access control list. The access control list specifies the remote IP address of the connecting load balancers and the remote IP address and port of the Agents that are allowed to connect.

  Specify the list of load balancers that are allowed to connect to the Advisor in the `lb_id_list` statement. Specify the list of Agents that are allowed to connect in the `agent_id_list` statement.

  Rules:

  - Specify only complete IP addresses in access control lists; subnetworks, IP prefixes, or other types of wildcards are not allowed.
  - The addresses in the `agent_id_list` statement must match the addresses in the `host_connection` statement of the Agents. For the purposes of high availability, the addresses specified in the `agent_id_list` statement of the Advisor and the `host_connection` statement of the Agents should be static or dynamic VIPAs, to tolerate individual link outages on the hosts.

Restriction: There is a maximum limit of 100 load balancers that can be connected to an Advisor at any given time.

- Policies

  You can establish policies using the z/OS Policy Agent so that the Agents, ADNR, or both are required to use TLS/SSL through AT-TLS for connections to the Advisor, and load balancers are required to use TLS/SSL.

  When you are using AT-TLS for all connections to the Advisor, the Advisor's `lb_id_list` and `agent_id_list` statements and the Agents' `host_connection` statements are optional. If you use these statements, the rules for access control list configuration statements still apply. AT-TLS is an alternative to using these statements, but you can still specify the statements. If you specify these statements and you are using AT-TLS, the statements are not required to match on the Advisor. For example, if an Agent connects using AT-TLS, the Advisor allows the connection to succeed even if the `agent_id_list` statement does not list that Agent.

Customizing optional statements

Customize the optional statements in the Advisor's configuration file.
The update_interval statement controls how often each Agent updates the Advisor with data, and depending upon load balancer implementation and configuration, can control how often load balancers are updated with information from the Advisor. The default value is 60 seconds. At each update interval, each Agent refreshes the Advisor with the status of each registered member for which the Agent is responsible. This information includes the status of the target application (active or not), whether it is an application member, the operator quiesce state of the member, and various weights that measure the target system and application’s ability to handle additional workload requests. The lower the update interval, the more up-to-date the load balancer's data will be with respect to the target's availability and capability to handle additional workload requests. Of course, the lower the update interval, the higher the network traffic and CPU overhead is.

Depending upon load balancer implementation and configuration, the update_interval statement might also determine how often the load balancer is updated with data from the Advisor. If the load balancer supports the SASP push flag, and it has been specified in the load balancer, the Advisor sends data to the load balancer at least every update interval. Regardless of what the update interval is set to, if this push flag is supported and configured in the load balancer, certain events might cause the Advisor to update the load balancer with information before the update interval timer expires. These events include the starting or stopping of a target application, or the addition or deletion of a member's IP address on the Agent host.

Therefore, the update interval is a key factor in determining the latency period between when changes occur on the target application system, and when the load balancer is informed of them. Each Agent updates the Advisor with new information every update interval. The Advisor, in turn, updates the load balancer with changes in weights every update interval, if the load balancer supports the push flag. In addition, if the push flag is supported and configured by the load balancer, the Advisor updates the load balancer with any change in the target’s availability status as soon as it discovers such a change from the Agent, instead of waiting for the update interval to expire. Therefore, when the load balancer supports and configures the push flag, the maximum amount of latency expected between a change in a member's weight and when the load balancer is informed of it is twice the update interval (that is, one update interval for the Agent to report it to the Advisor and one update interval for the Advisor to report it to the load balancer). However, on the average, it should take one update interval for a change in the target application weight to reach the load balancer.

Use the optional wlm statement to specify the default type of WLM recommendation to be used for all groups. There are two choices for this, the basewlm and serverwlm values. If you do not specify this statement, the default is basewlm. If you want a specific group of applications to use a type of WLM recommendation other than the default, you can override the default WLM recommendation type for that group on a port number basis using the port_list statement. The WLM recommendation is a key component used in determining the net weight assigned to a member.

The type of WLM recommendation represented by the basewlm value indicates the overall displaceable capacity (general, zAAP, and zIIP) of the system where the application represented by the member is, relative to the other systems in the sysplex. This is referred to as a WLM system weight recommendation. Use the optional proctype parameter with basewlm to specify the proportion of general, zAAP, and zIIP CPU that is consumed by an application's workload.

The serverwlm value represents a different type of WLM recommendation, in that it reflects how well an individual server application is performing from a WLM perspective (based on the WLM policy). This type of recommendation is a server-specific recommendation and is referred to as a server-specific WLM recommendation. Server-specific WLM recommendations are composed of two key elements:

- The amount of displaceable capacity (general, zAAP, and zIIP) available on the target system based on the importance level of the application, and the proportion of general, zAAP, and zIIP CPU that is currently being consumed by the application’s workload. For example, if the application is using only general and zAAP CPU, the displaceable zIIP capacity is not considered.

- How well the application is performing compared to the WLM goals for that application workload.

In addition, WLM provides an interface that enables applications to report the following additional information:

- Abnormal transaction completion rate, or the rate of abnormal completions per 1000 total transactions
• Application health, a value in the range 0–100% (100% being optimal), representing the overall health of the application

Using this additional information, WLM might reduce the server-specific recommendation. For more information, see “Sysplex distributor” on page 455.

Evaluate whether you can use WLM server-specific distribution as an alternative to WLM system weight distribution for an application. In addition to the above reasons, server-specific distribution has the added advantage that processor proportions are automatically determined and dynamically updated by WLM, based on the actual CPU usage by the application. If you need to use system weight distribution, to determine the processor proportions to configure, study the workload usage of assist processors by analyzing SMF records, using performance monitors reports such as RMF, and so on.

System members (port and protocol are zero) always use WLM system weight recommendations and cannot be configured to consider zAAP and zIIP CPU, because the type of workload is unknown. This is true even if proctype is coded on the wlm statement.

Application members can use either type.

It is important that you choose the type of WLM recommendation that is best suited to each group of applications. Some types of applications are better suited to using WLM system weight recommendations rather than server-specific WLM recommendations. For most applications, server-specific WLM recommendations provide a more accurate way to distribute workload to their servers. However, when a server acts as an access point to applications that run in other address spaces (and therefore in a different service class), WLM system weight recommendations might be the preferred distribution method; if expected usage of general, zAAP, and zIIP processors is known, this recommendation can be further refined by using the proctype parameter. The sysplex distributor function can also use server-specific WLM recommendations or WLM system weight recommendations. For examples of some applications that might be better represented by WLM system weight recommendations, see “Sysplex distributor” on page 455.

The optional port_list statement enables you to override or specify parameters for members on a port number basis. The wlm parameter of the port_list statement enables you to override the value defined (or specified by default) on the wlm statement, for all members that use the port number specified. The actual WLM recommendation type used is still dependent upon the value specified and the z/OS level of the Agents owning the members of the group.

When selecting the type of WLM recommendation to use for a given group, it is important to consider the following requirements:

• All members in a group must specify the same type of WLM recommendation (using the wlm or port_list statement).

• To use server-specific recommendations, no Agent reporting on behalf of a member of a group can be at a release level prior to z/OS V1R7.

For any groups where these requirements are not met, the Advisor uses WLM system weight recommendations, and a warning message is written to syslogd. The main rationale behind this is that WLM system weight recommendations and server-specific WLM recommendations cannot be directly compared to one another.

The Advisor can detect dynamically whether these requirements are being met. For example, if all owning Agents of a group, except one, support server-specific WLM recommendations, and the application on that one system is brought down, the WLM recommendation type would change dynamically from WLM system weight recommendations to server-specific WLM recommendations, provided the Advisor was configured to request server-specific WLM recommendations for that group. Similarly, if that same application is started back up, the WLM recommendation type would dynamically switch back to WLM system weight recommendations. A similar circumstance would arise if the member owned by the Agent that does not support server-specific WLM recommendations was quiesced by the z/OS operator or the load balancer administrator.

The optional debug_level statement determines how much trace data is captured in the Advisor's log file.
**Restriction:** In most cases, you should not customize the debug_level statement, unless directed to do so by an IBM Service representative. Adding additional types of trace data can cause the amount of data captured to become voluminous. Reducing the amount of trace data from the default might make diagnosing a problem more difficult.

For more details on the Advisor configuration file statements, see *z/OS Communications Server: IP Configuration Reference*.

**Configuring one Advisor per sysplex in a CINET environment**

You must define listening sockets and ports, as described in “Define listening sockets/ports (required)” on page 1126.

**Rule:** If you use a unique application-instance DVIPA for the Advisor in a CINET environment, all TCP/IP stacks on that system must code the VIPARANGE statement for that DVIPA. Alternatively, and less desirably, you can establish stack affinity to one of the TCP/IP stacks that are coded with the VIPARANGE statement for that DVIPA, if you do not have VIPARANGE coded for that DVIPA on all of the TCP/IP stacks on that system. This alternative, of course, does not enable the Advisor to be moved to another TCP/IP stack in the event of failure, unless you are able to restart the Advisor with a different start procedure that can establish stack affinity to another TCP/IP stack that has the DVIPA defined in a VIPARANGE statement. For information on the use of the _BPXK_SETIBMOPT_TRANSPORT environment variable that can be used to establish stack affinity, see “Generic server versus server with affinity for a specific transport provider” on page 46.

The lb_connection_v6 statement does for IPv6 what the lb_connection_v4 statement does for IPv4. You can specify either or both of these statements. If you run the Advisor on a CINET system, be aware that the address or addresses you choose for these statements tie the Advisor to the stack owning those addresses. Consequently, termination of that stack results in termination of the Advisor.

**Configuring Advisors in a subplexing environment**

When you are using subplexing, there can be more than one Advisor active in the sysplex at any given time. In fact, there should be one Advisor active for each subplex in the sysplex that you want to participate in load balancing through the Load Balancing Advisor. Each Advisor reads configuration data from a file, which can exist as a z/OS UNIX file, a PDS or PDSE member, or a sequential data set. In the configuration file for each Advisor, the sysplex_group_name statement specifies the TCP/IP sysplex group name, in the form EZBTvvt, where vv is the VTAM subplex group ID specified on the VTAM XCFGRPID start option, and tt is the TCP/IP subplex group ID specified by the XCFGRPID parameter on the GLOBALCONFIG statement in the TCP/IP profile. If no VTAM subplex ID is specified when VTAM is started, then vv is CP. If no TCP/IP subplex ID is specified in the TCP/IP profile, then tt is CS. If you have a default subplex in your sysplex (that is, a subplex in which both the VTAM and TCP/IP subplex IDs are not specified), configure the Load Balancing Advisor for that subplex with a sysplex group name of EZBTCPCS.

**Requirement:** In a subplexing environment, the IP address of the Advisor’s listening socket must exist on a TCP/IP stack belonging to the subplex that corresponds to the TCP/IP sysplex group name specified in the Advisor’s configuration file. If there is more than one TCP/IP stack in a subplex, the IP address must be a DVIPA defined within a VIPARANGE statement on each of the stacks in the subplex. This enables the Advisor to connect regardless of the order that the TCP/IP stacks in the subplex are started.

**Tip:** In a subplexing environment, if you will have more than one Advisor started on the same z/OS system (in different subplexes), create unique start procedures for them or ensure that they have unique job names when they are started (for example, S LBADV.ADV0105 or S LBADV, JOBNAME=ADV0105).

**Step 4: Configure one Agent per z/OS system in the sysplex**

There can be only one Agent active per z/OS system in the sysplex at any point in time, unless sysplex subplexing is used. When operating in a sysplex subplexing environment, this step requires additional actions. For information about the changes to this step, see “Configuring Agents in a subplexing environment” on page 1132.
The Agent reads configuration data from one file, which can exist as a z/OS UNIX file, a PDS or PDSE member, or a sequential data set. The Agent configuration file is specified on the CONFIG DD statement in the Agent start procedure. A sample start procedure is provided in EZBLBAGE in SEZAINST.

The Agent configuration file serves three basic purposes:

- Defines the IP address and port that the Agent binds to for communication with the Advisor
- Identifies the location (IP address and port) of the Advisor
- Customizes optional parameters

A sample Agent configuration file is provided in EZBLBAGC in SEZAINST.

The Advisor and Agent statements define addresses and ports on the local system and on remote systems. At times, it can be difficult to remember which statements refer to local sockets and which statements refer to remote addresses and ports.

**Tip:** Any statement containing the word `connection` refers to a local socket, and any statement containing the word `id` refers to a remote address and possibly port.

**Defining the IP address and port to bind to for communications with the Advisor**

Specify the local IP address and port that the Agent binds to for communications with the Advisor on the `host_connection` statement. This is used as part of the Advisor's access control enforcement.

**Rules:**

- The IP address on the `host_connection` statement can be an IPv6 address, if the Agent's system is running an IPv6-enabled TCP/IP stack and the Advisor has an IPv6-enabled TCP/IP stack available.
- If an IPv4 address is specified on the `host_connection` statement, an IPv4 address must be specified on the `advisor_id` statement. Similarly, if an IPv6 address is specified on the `host_connection` statement, an IPv6 address must be specified on the `advisor_id` statement.

**Guidelines:**

- For simplicity and consistency, you might want to specify the same port on the `host_connection` statement for each Agent, and reserve the same port for the Agent on each TCP/IP stack that an Agent will run on. For more information about port reservation, see “Step 5: Customize the TCP/IP profiles of the TCP/IP stacks on which the Advisor and Agents are to run (optional)” on page 1133.
- The address in the `host_connection` statement (and therefore, also in the Advisor’s `agent_id_list` statement) should be a static VIPA. For CINET considerations regarding the `host_connection` statement, see “Configuring one Agent per z/OS system in the sysplex in a CINET environment” on page 1132.

The Agent `host_connection` statement and the Advisor `agent_id_list` statement are optional if AT-TLS is used for all Agent-Advisor connections. If you specify these statements, the rules and guidelines previously stated still apply. AT-TLS is an alternative to using these statements, but you can still specify the statements. If you specify these statements and you are using AT-TLS, the statements are not required to match on the Advisor. For example, if an Agent connects using AT-TLS, the Advisor allows the connection to succeed even if the `agent_id_list` statement does not list that Agent.

Also see “Configuring one Advisor per sysplex in a CINET environment” on page 1130 for CINET considerations regarding unique application-instance DVIPAs and stack affinity.

**Restriction:** If the Advisor is using IPv6 for the load balancer connections, or if any Agents are using IPv6 to connect to the Advisor, movement of the Advisor is limited to IPv6–enabled TCP/IP stacks.

**Identifying the location of the Advisor (required)**

Specify the location of the Advisor on the `advisor_id` statement. This statement contains an IP address and port that the Advisor uses to listen for connections from Agents in the sysplex.

**Guideline:** Use a dynamic VIPA for this address, to enable the Advisor to be moved within the sysplex in the event of a failure of the Advisor or the Advisor’s underlying system.

**Rules:**
• The port specified on the advisor_id statement must match the port specified on the Advisor's agent_connection_port statement.

• If an IPv4 address is specified on the advisor_id statement, an IPv4 address must be specified on the host_connection statement. Similarly, if an IPv6 address is specified on the advisor_id statement, an IPv6 address must be specified on the host_connection statement.

**Customizing optional statements**

Similar to the Advisor, the optional debug_level statement determines how much trace data is captured in the Agent's log file.

**Restriction:** In most cases, you should not customize this statement, unless directed to do so by an IBM Service representative. Adding additional types of trace data can cause the amount of data captured to become voluminous. Reducing the amount of trace data from the default might make diagnosing a problem more difficult.

For more details on the Agent configuration file statements, see z/OS Communications Server: IP Configuration Reference.

**Configuring one Agent per z/OS system in the sysplex in a CINET environment**

If the system where the Agent is running is a CINET system, the address in the host_connection statement (and therefore, also in the Advisor's agent_id_list statement) should be a dynamic VIPA (DVIPA) to facilitate movement of the Agent to another TCP/IP stack on that system.

**Rule:** If you use a unique application-instance DVIPA (coded with VIPARANGE) for the Agent in a CINET environment, all TCP/IP stacks on that system must code the VIPARANGE statement for that DVIPA. When configured in this manner, if the TCP/IP stack that currently owns the DVIPA fails, the Agent remains up and automatically attempts to bind again to the DVIPA. The next available default TCP/IP stack becomes the new owner of the DVIPA. (If this is a sysplex subplexing environment, all TCP/IP stacks on that system that are within the same subplex as the Agent must code the same VIPARANGE statement for that DVIPA. This allows the Agent to reestablish connectivity with the Advisor through another stack in the same subplex on that system.) Alternatively, and less desirably (see following restriction), you can establish stack affinity to one of the TCP/IP stacks that are coded with the VIPARANGE statement for that DVIPA, if you do not have VIPARANGE coded for that DVIPA on all of the TCP/IP stacks on that system. Of course, this does not enable the Agent to be automatically moved to another TCP/IP stack in the event of failure. To recover the Agent in this type of configuration, manual intervention (or automation) is required. Because the Agent remains active if its TCP/IP stack fails, you must manually terminate the Agent. Then you must restart the Agent with a different start procedure that can establish stack affinity to another available TCP/IP stack. For information on the use of the _BPXK_SETIBMOPT_TRANSPORT environment variable that can be used to establish stack affinity, see “Generic server versus server with affinity for a specific transport provider” on page 46.

**Restriction:** When running in a CINET environment, establishing stack affinity between the Agent and one of the TCP/IP stacks on that system makes it easier to participate in workload balancing. The Agent running on that system is not aware of resources on the other TCP/IP stacks on that system. If you want to enable resources on all TCP/IP stacks in a CINET environment to participate in workload balancing, do not establish stack affinity with the Agent.

**Configuring Agents in a subplexing environment**

When you are using subplexing, there can be more than one Agent per z/OS system in the sysplex. In fact, there should be one Agent active for each subplex with a TCP/IP stack on a system that you want to participate in load balancing through the Load Balancing Advisor. Each Agent reads configuration data from a file, which can exist as a z/OS UNIX file, a PDS or PDSE member, or a sequential data set. In the configuration file for each Agent, the sysplex_group_name statement specifies the TCP/IP sysplex group name, in the form EZBTVVTT, where \( \nu \) is the VTAM subplex group ID specified with the VTAM XCFGRPID start option, and \( \tau \) is the TCP/IP subplex group ID specified with the XCFGRPID parameter on the GLOBALCONFIG statement in the TCP/IP profile. If no VTAM subplex ID is specified when VTAM is started, then \( \nu \) is CP. If no TCP/IP subplex ID is specified in the TCP/IP profile, then \( \tau \) is CS. If you have a default
subplex in your system (that is, a subplex in which both the VTAM and TCP/IP subplex IDs are not specified), configure the Load Balancing Agent for that subplex with a sysplex group name of EZBTPCPS.

Tip: In a subplexing environment, if you will have more than one Agent started on the same z/OS system (in different subplexes), create unique start procedures for them or ensure that they have unique job names when they are started (for example, S LBAGENT.AGE0105 or S LBAGENT, JOBNAME=AGE0105).

Requirements:

• In a subplexing environment, the IP address used by the Agent to connect to the Advisor must exist on a TCP/IP stack belonging to the subplex that corresponds to the TCP/IP sysplex group name specified in the Agent’s configuration file. If there is more than one TCP/IP stack in a subplex, the IP address must be a DVIPA defined within a VIPARANGE statement on each of the stacks in the subplex. This enables the Agent to connect regardless of the order that the TCP/IP stacks in the subplex are started.

• If you have more than one stack on a system, those stacks are not all in the same subplex, and you will be starting Load Balancing Agents on that system, the system must not be at a level prior to V1R10.

Step 5: Customize the TCP/IP profiles of the TCP/IP stacks on which the Advisor and Agents are to run (optional)

When operating in a sysplex subplexing environment, this step requires additional actions. For information about the changes to this step, see “Customizing TCP/IP profiles in a subplexing environment” on page 1138.

There are several things to do to customize the TCP/IP profile to accommodate the Advisor and Agents.

• In the appropriate TCP/IP profiles that they will use, including the TCP/IP stacks that they could potentially move to, reserve the ports that the Advisor and Agents will use. All ports for the Advisor and Agent use the TCP protocol, and thus should be reserved for TCP. The Advisor has at least two ports, and potentially three ports, to reserve, including the ports specified on the following statements:
  – lb_connection_v4
  – lb_connection_v6
  – agent_connection_port

  For CINET considerations regarding the lb_connection_v4 and lb_connection_v6 statements, see “Customizing TCP/IP profiles in a CINET environment” on page 1137.

• If you use dynamic VIPAs for the Advisor as recommended, you need to configure the appropriate TCP/IP profiles in the sysplex for the DVIPA definition and usage. The preferred definitions would include VIPADEFINE with MOVEABLE IMMEDIATE, or VIPARANGE with MOVEABLE NONDISRUPTIVE. For more specific information, see “Using dynamic VIPAs” on page 355.

Restriction: Do not mix sysplex distributor functions with these DVIPAs.

• If you are currently using the SHAREPORT or SHAREPORTWLM parameters on the TCP/IP profile PORT statement to enable multiple TCP applications to share the same port, some additional considerations might apply to your configuration. For example, if the TCP applications sharing the same port are also members of groups that are being reported to external load balancers with SASP, it is important to ensure that consistent criteria are used by the various load balancing components.

When using the z/OS Load Balancing Advisor, all instances of a TCP application sharing the same port on a target system are reported to external load balancers using a single member entry, and therefore, a single recommendation. This recommendation reflects the average net weight calculated for all the servers sharing the same port on a target system, and is based on the type of WLM recommendation configured on the Advisor. When the TCP connection requests reach a target TCP/IP stack and multiple applications are sharing the same port, the connections are then load balanced by TCP/IP across the multiple application server instances. How this load balancing is performed depends on whether the SHAREPORT or SHAREPORTWLM parameter is specified on the PORT statement. For more details on the PORT statement, see z/OS Communications Server: IP Configuration Reference.

Guideline: If server-specific WLM recommendations are configured within the Advisor for a given group that contains servers that share the same port on a given system or TCP/IP stack, the SHAREPORTWLM...
parameter should also be specified on the PORT statement in the TCP/IP profile for these servers. This enables both the external load balancers and the internal TCP/IP load balancer to operate with the same type of recommendations when load balancing work requests to these servers. Similarly, if WLM system weight recommendations were configured in the Advisor for a group, the SHAREPORT parameter would probably be more appropriate.

**Enabling TLS/SSL for z/OS Load Balancing Advisor (optional)**

For AT-TLS, the following customization tasks are required before starting the TCP/IP stacks and the Advisor and Agent applications:

- Enable AT-TLS in the TCP/IP stack.
  
  Specify the TTLS parameter on the TCPCONFIG statement in the TCP/IP profile. For additional information about AT-TLS, see Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1093. For information about the TCPCONFIG statement, see z/OS Communications Server: IP Configuration Reference.

- Set up authorization for the `pasearch` command, if the command will not be issued from a superuser.
  
  Create a SERVAUTH profile of `EZB.PAGENT.sysname.image.ptype`, where the `ptype` value is set to TTLS or to a wildcard value. For more information, see “Steps for configuring the Policy Agent” on page 780 and z/OS Security Server RACF Security Administrator’s Guide.

- Enable AT-TLS configuration for the Policy Agent.
  
  Specify the CommonTTLSConfig and TTLSConfig statements in the Policy Agent configuration file for each stack. On the TTLSConfig statement, specify the path of the stack-specific AT-TLS policy file to be installed for the server. For additional information about the CommonTTLSConfig and TTLSConfig statements, see z/OS Communications Server: IP Configuration Reference.

- Define AT-TLS policies in new or existing Policy Agent configuration files.
  
  Specify the AT-TLS policies in the configuration files that are identified with the CommonTTLSConfig and TTLSConfig statements. Ensure that the Load Balancing Advisor policy definitions are defined on all systems in the sysplex on which the Advisor can run.

The Load Balancing Advisor is a server application. For general information about setting up AT-TLS for a server, see Table 58 on page 1098.

The following example shows the TTLSConfig policy file statements in the path file for the load balancer connections to the Advisor. Port 3860 is the default port.

```
TTLSRule        LBAvisorLBRule
{                
  LocalPortRange 3860
  Direction       Inbound
  TTLSGroupActionRef LBAvisorLBGroup
  TTLSEnvironmentActionRef LBAvisorLBEnvironment
}
TTLSGroupAction LBAvisorLBGroup
{                
  TTLSEnabled    On
}
TTLSEnvironmentAction LBAvisorLBEnvironment
{                
  TTLSKeyRingParms
  {                
    Keyring        server_key_ring
  }
  TTLSEnvironmentAdvancedParms
  {                
    # TTLS will verify a user ID is associated with certificate
    ClientAuthType SAFCheck
    ApplicationControlled On
  }
  HandshakeRole ServerWithClientAuth
  TTLSCipherParmsRef RequireEncryption
  Trace         7
}                
```
In this example, all external load balancers must use TLS/SSL and supply a client certificate that will be validated in the key ring and must be associated with a user ID on the SAF-compliant security product on the local z/OS system. This type of policy allows additional finer-grain SAF checks using optional SERVAUTH profiles. You can use other, less restrictive, policies; however, if you use less restrictive policies, the Advisor, Agent, and ADNR require that you specify the configuration parameters for those connections (lb_id_list or agent_id_list statements in the Advisor configuration file, host_connection statement in the Agent configuration file, and host_connection_addr statement in the ADNR configuration file).

The following example shows the TTLSConfig policy file statements in the path file for the Agent connections to the Advisor. Port 8100 is the port that is used in the sample Advisor configuration file:

```
TTLSRule LBAAdvisorAgentRule
{" LocalPortRange 8100
  Direction Inbound
  TTLSGroupActionRef LBAAdvisorAgentGroup
  TTLSEnvironmentActionRef LBAAdvisorAgentEnvironment
}
TTLSGroupAction LBAAdvisorAgentGroup
{" TTLSEnabled On
}
TTLSEnvironmentAction LBAAdvisorAgentEnvironment
{" TTLSKeyRingParms
   { Keyring server_key_ring
   }
  TTLSEnvironmentAdvancedParms
  { # TTLS will verify a user ID is associated with certificate
    ClientAuthType SAFCheck
    ApplicationControlled On
  }
  HandshakeRole ServerWithClientAuth
  TTLSCipherParmsRef RequireEncryption
  Trace 7
}
# Set of TLS Ciphers with Encryption
TTLSCipherParms RequireEncryption
{" V3CipherSuites TLS_RSA_WITH_RC4_128_MD5
  V3CipherSuites TLS_RSA_WITH_RC4_128_SHA
  V3CipherSuites TLS_RSA_WITH_DES_CBC_SHA
  V3CipherSuites TLS_RSA_WITH_3DES_EDE_CBC_SHA
}
```

The Load Balancing Agent is a client application. For general information about setting up AT-TLS for a client, see Table 59 on page 1100.

You must configure the policy on the TCP/IP stack where the Agents will run with the same SSL protocol, key ring, and cipher suite (if encrypting data) for which the Advisor is configured.

The following example shows the TTLSConfig policy file statements for a Load Balancing Agent. On the TTLSConfig statement, specify the path of the stack-specific AT-TLS policy file to be installed for the client. For more information about the TTLSConfig statement, see z/OS Communications Server: IP Configuration Reference. Port 8100 is the port that is used in the sample Agent configuration file:

```
TTLSRule LBAgentRule

```
Create z/OS server (Advisor) and client (Agent, ADNR, external load balancer) key rings and necessary certificate authority certificates.

The server key ring needs to contain a server certificate, and any certificates that are used to sign it. The server needs access to the private keys of the server certificate. The client key ring needs the root certificate that is used to sign the server certificates.

For a TLS/SSL primer and some step-by-step examples, see Appendix B, “TLS/SSL security,” on page 1299. For more information about managing key rings and certificates with RACF and the RACDCERT command, see z/OS Security Server RACF Security Administrator’s Guide.

Send the external load balancer’s certificate to the z/OS host.

Associate each user ID (for the Advisor, Agents, ADNRs, and external load balancers) with a certificate.

Use the RACDCERT ADDRING command to define a key ring in RACF and to associate it with your application’s user ID. Use the RACDCERT CONNECT command to connect certificates to the key ring. For detailed information about setting up your certificate environment, see z/OS Security Server RACF Security Administrator’s Guide.

Create client side certificates for the external load balancers. See the load balancer documentation for instructions.

Define client user IDs on the TCP/IP stacks on which the Advisor will run by issuing security product commands to establish authorization for the user IDs.

You can configure the Advisor’s clients (Agents, ADNR, and external load balancers) to present security credentials, including a user ID. If you configure this, you must set up the security manager on the Advisor system to accept these credentials.

Using a security product like RACF, perform the following steps to control access to the Load Balancing Advisor, Agents, and ADNR.

1. Use the following commands to ensure that the SERVAUTH class is active and RACLISTed, and that RACLIST processing is enabled:

```
SETROPTS CLASSACT(SERVAUTH)
SETROPTS RACLIST (SERVAUTH)
```
2. Use the following commands to define the following SERVAUTH class profiles on each system on which the Advisor might run.

```
RDEFINE SERVAUTH EZB.LBA.LBACCESS.sysname.tcpsysplexgroupname UACC(NONE)
RDEFINE SERVAUTH EZB.LBA.AGENTACCESS.sysname.tcpsysplexgroupname UACC(NONE)
```

where sysname is the MVS system name or a wildcard (*) and tcpsysplexgroupname is the TCP/IP sysplex group name. If you are not using subplexing, use the default subplex identifier EZBTCPCS or a wildcard (*). For example, on system MVSSYS using the default subplex, the profile name is EZB.LBA.LBACCESS.MVSSYS.EZBTCPCS.

3. Use the following commands to grant access to the SERVAUTH class for the user IDs associated with the Agents, ADNR, and the external load balancers on each system on which the Advisor might run:

```
PERMIT EZB.LBA.LBACCESS.sysname.tcpsysplexgroupname -
   CLASS(SERVAUTH) ACCESS(READ) ID(userid)
PERMIT EZB.LBA.AGENTACCESS.sysname.tcpsysplexgroupname -
   CLASS(SERVAUTH) ACCESS(READ) ID(userid)
```

4. Use the following command to refresh the SERVAUTH class:

```
SETROPTS RACLIST(SERVAUTH) REFRESH
```

For specific instructions, see the EZARACF sample in SEZAINST.

Requirements:

- The AT-TLS policies and SERVAUTH profiles must be coordinated to provide the appropriate level of security. For example:
  - If a connection is presented to the Advisor and the AT-TLS check indicates that this is not a secure connection, then no subsequent SAF check is performed but an IP address ACL check (using the statements in the Load Balancer Advisor configuration files) is performed. If the IP address ACL check is successful, the connection is accepted.
  - If you always want a SAF level check to be performed, then ensure that the AT-TLS policy requires client certificates that are associated with user IDs defined on the local SAF-compliant security product. Also ensure that the SAF profile is defined and the correct user IDs are permitted READ access to the profile. If a secure connection is presented to the Advisor, and the SAF profile exists but the user ID is not authorized to the profile, then the connection will fail and no ACL check will be performed.
  - If the SERVAUTH profile is not defined, then the Load Balancer Advisor performs the IP Address (and port where appropriate) access control list checks before permitting a connection to the Load Balancer Advisor.
  - If the Advisor might run on more than one system, perform set up on all those systems or use a wildcard (*).

For additional information, see z/OS Security Server RACF Security Administrator's Guide.

Customizing TCP/IP profiles in a CINET environment

The Advisor can use multiple TCP/IP stacks in a CINET environment. The addresses specified in the `lb_connection_v4` and `lb_connection_v6` statements can belong to different TCP/IP stacks. Moreover, because the socket that listens for Agent connections uses the IPv4 or IPv6 unspecified address, the TCP/IP stack or stacks that incoming Agent connections use depends upon the IP addresses specified in the Agents' `agent_id_list` statements. To simplify your configuration and to make Advisor outages that are the result of a TCP/IP stack failure or termination more predictable and recoverable, all incoming connections to the Advisor should use a single TCP/IP stack. Therefore, the addresses you specify in the `lb_connection_v4` and `lb_connection_v6` statements should belong to the same TCP/IP stack, and you should configure all load balancers and Agents to use these same IP addresses when connecting to the Advisor. The addresses you specify should be dynamic VIPAs to enable the movement of the Advisor in case of failure. This implies that these dynamic VIPAs should be defined in the TCP/IP profiles of all the stacks using a VIPARANGE statement. If the Advisor is restarted as a result of failure in a given TCP/IP stack, the Advisor will be configured to use the same VIPAs that were in effect when it was last used. This ensures that the Advisor can be restarted in a state that is consistent with its previous state, and that it can connect to the same load balancers and Agents that were used previously.
stack, the dynamic VIPAs are then activated on another TCP/IP stack in that system. If you decide to use the IPv4 or IPv6 unspecified addresses for the lb_connection_v4 and lb_connection_v6 statements, you should use the BIND parameter on the PORT reservation statement to bind these sockets to the dynamic VIPA on the one TCP/IP stack you have decided to use.

Customizing TCP/IP profiles in a subplexing environment

In a subplexing environment, each Advisor and Agent must use a TCP/IP stack that is in its associated subplex. That stack should specify the TCP/IP subplex group ID that corresponds to the TCP/IP part (tt) of the sysplex_group_name (EZBTvtt) for which the Advisor or Agent has been configured. The DVIPA for the Advisor must be defined in all the stacks that are associated with the subplex, where a restart of the Advisor can occur.

Step 6: Customize WLM policies for the Advisor and Agents (optional)

It is important that the Advisor and Agents receive an adequate amount of system resources to properly balance workloads. Part of this task involves making the Advisor and Agent run non-swappable. In addition, WLM can control the amount of system resources allocated to the Advisor and Agents.

Guideline: The Advisor and Agents should be assigned to the WLM SYSSTC service class to receive the appropriate dispatching priority. For more information about categorizing work into service classes, see z/OS MVS Planning: Workload Management.

Step 7: Configure the external load balancers

Configure the load balancers with the location (IP address and port) of the Advisor. For maximum availability, this address should be defined as a DVIPA.

In a sysplex subplexing environment, this step requires additional actions. For information about the changes to this step, see “Configuring the external load balancers in a subplexing environment” on page 1140.

If you are using TLS/SSL, the load balancers are client applications in a z/OS Load Balancing Advisor environment. You must configure the load balancers with the same TLS/SSL protocol and cipher suite (if encrypting data) with which the Advisor is configured. Client certificates should be configured on the load balancer, and also defined in the z/OS SAF-compliant security product if that level of authentication is required. See the load balancer documentation for instructions.

Restrictions:

- If the Advisor is using IPv6 for the load balancer connections, or if any Agents are using IPv6 to connect to the Advisor, movement of the Advisor is limited to IPv6–enabled TCP/IP stacks.
- There is a maximum limit of 100 load balancers that can be connected to an Advisor at any given time.

You might be able to customize features of the load balancer’s communication with the Advisor. The SASP protocol defines two features that the load balancer implementation might or might not allow to be configured. One determines whether the load balancer polls the Advisor for updated data, or whether updated data is pushed to the load balancer. The other determines whether only members that have updated data should be sent to the load balancer, or whether all members should be sent to the load balancer regardless of whether their data has changed or not. To determine whether these features can be customized, and how to perform the customization if available, consult your load balancer’s documentation. If the load balancer is capable and configured to request that the Advisor push updated information to the load balancer, the Advisor will update the load balancer at least every update interval. If the load balancer is capable and configured to poll the Advisor for updated information, the Advisor will recommend to the load balancer that it poll every update interval. However, the load balancer can choose to disregard this guideline. Consult the load balancer documentation for the expected behavior in these circumstances.

You might want to consider having redundant load balancers configured alike for availability reasons. If so, you need to be aware of the load balancer’s unique load balancer identifier (LB UID), sometimes referred to as the UID or UUID, which uniquely identifies a load balancer. Duplicate LB UIDs are not allowed and connection attempts to the Advisor from a load balancer using the same LB UID as an
existing connection will force the existing connection to be broken and replaced by the new connection. Redundantly configured load balancers either need to have unique LB UIDs, if you want them to serve as hot standbys that are connected simultaneously along with the load balancer they are backing up, or if they are configured with the same LB UID, they must remain unconnected from the Advisor until the original load balancer fails.

Some load balancers might be capable of using either dispatch or directed mode when forwarding packets to their destinations. External load balancers typically use a cluster IP address to represent the set of applications being load balanced. Client applications use this cluster IP address as the destination IP address for their requests. When a load balancer uses dispatch mode, the destination IP addresses for incoming IP packets is not changed. Instead, the load balancer forwards the packet to a target z/OS system by using the MAC address of a network adapter on that system. The receiving z/OS system inspects the destination IP address of the packet, and if it matches one of the IP addresses in its HOME list, accepts the packet. As a result, with dispatch mode, all target z/OS systems must have the load balancer’s cluster IP address defined in their HOME list. However, it is important that these addresses are not advertised externally through dynamic routing protocols. One way to accomplish this is by defining these IP addresses as loopback addresses on z/OS.

With directed mode, the load balancer converts the destination IP address (that is, the cluster IP address) to an IP address owned by the target z/OS system, using technologies such as network address translation (NAT). When IP packets for these connections are sent back to clients, the load balancer converts the source IP address (that is, the target z/OS system’s IP address) back to the cluster IP address that the application had used on its request.

While dispatch mode eliminates the need for performing NAT, it does have some special considerations. For example, in Figure 142 on page 1157, both SYSA and SYSB have the same server, FTPD, bound to the same port number using INADDR_ANY. The packet will have the cluster IP address (both SYSA and SYSB are in the same cluster), so the load balancer will use the MAC address to decide to send the packet to SYSA or SYSB, and TCP/IP will then route the packet to the server.

**Restrictions:** When using dispatch mode, for the load balancer to function correctly, there are the following limitations:

- An OSA can be shared among LPARs only if Virtual MAC (VMAC) addressing is configured for each TCP/IP target stack sharing the OSA.
- All target applications must bind to the IP address specified by INADDR_ANY or in6addr_any, and the cluster IP address must be defined to the stack; however, this must be done so that the address is not advertised (as in a loopback address).

If these restrictions are not met, load balancing will not be optimal because some servers will not get work routed to them.

With directed mode, either the destination IP address (server NAT) is modified in the packet itself, or both the destination and source IP addresses (server NAT and client NAT) are modified in the packet. The packet must return through the same load balancer that will recognize the changes and do the reverse mapping, so a packet can flow from the original destination to the original source.

Configure each load balancer with the members that represent the individual target application instances, or system members that generically represent a system in the sysplex, or both. Members that can share the same type of workload are defined under the same group. For example, TN3270E Telnet servers are defined under one group, and HTTP servers in another. Application members are defined by specifying an IP address, a nonzero port, and a nonzero protocol. System members are defined by specifying an IP address, and specifying the port and protocol to be zero. Members that have only a port of zero or only a protocol of zero (that is, one but not both are zero) are not considered valid members and will not receive any data from the Advisor. The IP addresses of the members must represent valid, reachable addresses within the sysplex that are unique to a specific sysplex system. This excludes such addresses as the loopback addresses, and other non-advertised addresses.

**Tip:** The Advisor does not check for improperly configured members. After the entire z/OS Load Balancing Advisor system is operational, display all members registered by each load balancer and verify each member you expect to be available is flagged as available. Screen any unavailable members for coding errors in the member, such as incorrect IP addresses, ports, or protocols.
**Guideline:** For availability reasons, the IP addresses configured for each member should be VIPA addresses (static or dynamic). If the IP address of a physical interface fails and a member specifies that IP address, the Advisor still indicates that the member is available, as alternate routing paths to that member might exist. However, if no alternate routing paths exist, workload requests cannot be delivered to the target system. By using static or dynamic VIPAs in members, the chance of an alternate route being available when a physical interface fails is greatly increased, as long as at least one physical interface is still available.

**Restrictions:**

- All IP addresses configured in members belonging to the same group must exist within the same sysplex.
- All members belonging to the same group must be of the same type. That is, all members must be application members or all must be system members.
- Certain classes of IP addresses must not be coded for members in the load balancer. This includes the following classes of addresses:
  - Distributed DVIPAs (the address specified on a VIPADISTRIBUTE statement). Defining members with these addresses would combine two load balancing methodologies for the same workload, wasting system resources.
  - Deprecated IPv6 addresses. These are flagged as such in a NETSTAT HOME display. It is probably safest to not code any autoconfigured IPv6 addresses within members.
  - Addresses that are not unique within the sysplex.
  - Addresses that are not reachable from the load balancer, including:
    - Loopback addresses.
    - Unavailable IPv6 addresses. These might be marked as unavailable if duplicate address detection is in progress, has failed, or the interface ID is unknown. These addresses are displayed in a NETSTAT HOME display, including the reason they are marked unavailable.

**Configuring the external load balancers in a subplexing environment**

You might configure separate load balancers for each subplex, if the subplexes represent connectivity to networks with different security domains. When configuring a load balancer with the IP address of a Load Balancing Advisor, ensure that you have connectivity from the load balancer to the subplex that the Load Balancing Advisor is handling. In addition, groups and target applications that the external load balancer requests information on should belong to the same subplex that the Load Balancing Advisor is handling.

**Steps for starting the z/OS Load Balancing Advisor**

Follow these steps to start the TCP/IP stacks that the Advisor and Agents are to use, the target applications, the Agents, the Advisor, and the load balancers.

**Procedure**

Perform the following steps to start the z/OS Load Balancing Advisor:

1. Start the TCP/IP stacks that the Advisor and the Agents will use.
   - See “Step 1: Start the TCP/IP stacks that the Advisor and the Agents will use” on page 1141.

2. Start the target applications that will be the targets of load balancing.
   - See “Step 2: Start the target applications that will be the targets of load balancing” on page 1141.

3. Start one Agent on each sysplex system that you want to participate in this method of workload balancing.
   - See “Step 3: Start one Agent on each sysplex system you want to participate in this method of workload balancing” on page 1141.

4. Start the one instance of the Advisor in the sysplex.
   - See “Step 4: Start the one instance of the Advisor in the sysplex” on page 1141.
5. Start the load balancers.
   See “Step 5: Start the load balancers” on page 1141.

**Step 1: Start the TCP/IP stacks that the Advisor and the Agents will use**

The TCP/IP stacks that the Advisor will use must be started prior to starting the Advisor. An Agent can be started before the TCP/IP stack it uses is started. If the TCP/IP stack that an Agent uses terminates, the Agent remains active and reestablishes communication with the TCP/IP stack after it becomes active again. For CINET considerations regarding Agent recovery after stack failure, see “Starting the TCP/IP stacks in a CINET environment” on page 1141.

**Starting the TCP/IP stacks in a CINET environment**

In a CINET environment, certain configurations might necessitate manual intervention for recovery if the Agent's TCP/IP stack fails. For more information, see the rule in “Configuring one Agent per z/OS system in the sysplex in a CINET environment” on page 1132.

**Step 2: Start the target applications that will be the targets of load balancing**

No modifications are necessary to these applications, their configurations, or start procedures, unless the load balancer is using dispatch mode for packet forwarding. For more information on dispatch mode, see “Step 7: Configure the external load balancers” on page 1138.

**Step 3: Start one Agent on each sysplex system you want to participate in this method of workload balancing**

It does not matter whether the Agents are started before the Advisor, or whether the Advisor is started before the Agents. If the Advisor is started after the Agents are started, the Agent periodically attempts to connect to the Advisor. Only one Agent can be started per z/OS system. Agents must be started from a start procedure as a started program (EXEC PGM=). They cannot be started under BPXBATCH. The IBM-supplied program properties table has entries to make the Agents run non-swappable. You should not override this entry to make the Agents run swappable.

**Starting Agents in a subplexing environment**

You can start more than one Agent on a z/OS system, if there are TCP/IP stacks for more than one subplex on that system.

**Step 4: Start the one instance of the Advisor in the sysplex**

As Agents connect to the Advisor, MVS console messages appear on the Advisor’s MVS console and on the Agents' MVS consoles. Verify that each Agent you expect to connect to the Advisor has connected. You can also use the NETSTAT,CONN command on the Advisor's TCP/IP stack to see which Agents are currently connected. The Advisor must be started from a start procedure as a started program (EXEC PGM=). It cannot be started under BPXBATCH. The IBM-supplied program properties table has entries to make the Advisor run non-swappable. You should not override this entry to make the Advisor run swappable.

**Starting Advisors in a subplexing environment**

You can start more than one Advisor in the sysplex, one for each subplex in the sysplex.

**Step 5: Start the load balancers**

When a load balancer has connected, messages appear on the Advisor's MVS console. You can also use the Advisor’s MODIFY proclname,DISPLAY,LB command to see which load balancers are connected to the Advisor. For details on the Advisor’s MODIFY command, see z/OS Communications Server: IP System Administrator’s Commands.

**Restriction:** There is a maximum limit of 100 load balancers that can be connected to an Advisor at any given time.
Verifying that the Advisor system is functioning correctly (optional)

View the MVS console of the Advisor and Agent systems after they are started to verify that the applications started correctly and are still running. If there are any failure messages, see the appropriate message description for the appropriate corrective action. View the syslogd files of the Advisor and Agent systems to see whether any error or warning messages were issued.

Use the following commands to verify that the Advisor system is functioning correctly:

• Verify that the Advisor is started and connected to the expected load balancers by issuing the Advisor's \texttt{MODIFY procname,DISPLAY,LB} command. Verify that each load balancer is displayed. Take note of the LB INDEX displayed for each load balancer. This identifier is needed to display details of the load balancer, including its registered groups and members.

  \textbf{Tip:} Individual load balancers are identified in displays by their load balancer index (LB Index), which is generated by the Advisor when the load balancer first connects. To display the details of a particular load balancer, first obtain the LB Index by displaying the list of all load balancers using the Advisor's \texttt{MODIFY procname,DISPLAY,LB} command. When you have the LB Index, display the details of a particular load balancer using the appropriate LB Index on the INDEX parameter as follows:

  \begin{verbatim}
  MODIFY procname,DISPLAY,LB,INDEX=lb_index
  \end{verbatim}

• Verify that each load balancer configured and registered the appropriate groups and members with the Advisor by issuing the following command:

  \begin{verbatim}
  MODIFY procname,DISPLAY,LB,INDEX=assigned_lb_index
  \end{verbatim}

  This display should show all groups and members defined to the load balancer.

• Verify that each Agent has started properly and is communicating with the Advisor. On each Agent, issue the following command:

  \begin{verbatim}
  MODIFY procname,DISPLAY,MEMBERS
  \end{verbatim}

  Each member that has an IP address owned by this Agent should appear in the display.

• Verify that the target applications that you want to load balance to are actually available for load balancing. On the Advisor, for each load balancer connected to the Advisor, issue the following command:

  \begin{verbatim}
  MODIFY procname,DISPLAY,LB,INDEX=assigned_lb_index
  \end{verbatim}

  Check for the AVAIL flag for each member in the display. The flag is either YES, meaning the member is available for load balancing, or NO, meaning it is not available for load balancing. To be available for load balancing, all of the following conditions must be true:

  – The Agent owning the member's IP address must be active and communicating with the Advisor.
  – The application must be active, if the member represents an application member, and must be on a TCP/IP stack that has not had eventual action message EZD1973E issued by sysplex problem detection and recovery. For more information, see “Problem detection” on page 437.
  – The member must not be quiesced by the Agent operator or the load balancer. The z/OS Agent operator is able to quiesce any member that is owned by that Agent. Also, depending upon load balancer implementation, it might be possible for the load balancer administrator to quiesce individual members.

  If one of the above conditions is false, correct the situation and repeat the display command until you are satisfied that all members that you intend to have available for load balancing are displayed as being available.

• Verify that the Advisor system is functioning correctly when using AT-TLS:

  – Use the \texttt{pasearch} command from the z/OS UNIX shell to query information from the Policy Agent. For example, \texttt{pasearch -t -r} displays active AT-TLS rule details. For more information about
displaying policy based networking information, see z/OS Communications Server: IP System Administrator's Commands.

- Use the Netstat TTLS/-x command to display z/OS Load Balancing Advisor, Agent, and ADNR AT-TLS policies. For more information about the Netstat TTLS/-x report, see z/OS Communications Server: IP System Administrator's Commands.

Operating the z/OS Load Balancing Advisor

When the Advisor and Agent are operational, you can monitor and customize processing:

- Change the logging level of the Advisor and Agents to suit your needs (optional)
- Interpret Agent and Advisor display information
- Stop distributing new workload requests (QUIESCE) to particular members or resume distribution (ENABLE) to those members (optional)

Changing the logging level of the Advisor and Agents

Optionally, you can change the logging level of the Advisor and Agents to suit your needs. The amount of information that is logged by the Advisor and Agents can be modified dynamically using the following command:

```plaintext
MODIFY procname,DEBUG,LEVEL=debug_level
```

However, modifying the logging level is not a step that should be taken lightly. The IBM default of 7 should not be changed unless instructed to do so by an IBM Service representative. For things to consider before modifying this value, see “Customizing optional statements” on page 1127.

Interpreting Agent and Advisor display information

Successfully interpreting the various flags and indicators that appear in Advisor and Agent displays can help you identify configuration problems, or might help explain why workloads are not being distributed as expected. For information on each field in the Advisor and Agent displays, see z/OS Communications Server: IP System Administrator's Commands. Some portions of the displays are described in more depth in Table 61 on page 1143, Table 62 on page 1146, and the subtopics that follow.

```

Figure 138. Sample output for the MODIFY procname,DISPLAY,LB command

**LB INDEX**

The LB index is generated by the Advisor to uniquely identify a load balancer, and is used in other MODIFY commands to display details of a particular load balancer. The LB index that is assigned to the next load balancer that connects can be difficult to predict at times, in case your automation attempts to predict them. Each time a load balancer connects, it is assigned a different LB index. At first, the numbers are assigned in order from 0 to 99, and then the numbers are reused. The next number assigned after 99 is based on a least-recently-used algorithm. Thus, of the load balancer connections that used the numbers 0-99, the index of the load balancer connection that ended first would be the next number assigned as the next LB index. This is done to prevent the confusion that could result if new load balancer connections obtained the lowest available index. If that were the case, it might be difficult to ascertain whether different load balancer displays referred to the same or different load balancer connection instances. If the Advisor is brought down and back up, the indexes start from zero again. Lines 3 and 6 in Figure 138 on page 1147 show two LB indexes. For more information about the LB INDEX field, see z/OS Communications Server: IP System Administrator's Commands.

**NOCHANGE, PUSH, TRUST**

All of these flags are set only by the load balancer. Whether they appear or not depends upon whether the particular load balancer implementation supports them, and if they are configured in the load balancer. The z/OS administrator has no control over the settings of these flags.

The NOCHANGE flag can affect the amount of data transferred between the load balancer and the Advisor. If this flag is set, only data that has changed since the last time data was sent to the load balancer is included. Consult the load balancer documentation to determine whether this setting is supported.

The PUSH flag can have an effect on how soon the load balancer is informed of certain events. If the PUSH flag is not on, the load balancer must poll the Advisor periodically for updates. If this flag is on, certain events can be communicated to the load balancer earlier than would be possible if polling were in effect. Those events include quicker notification of a target application being taken out of service, and quicker notification of when the member's IP address has been moved to another system in the sysplex (VIPA takeover) or removed entirely. When the PUSH flag is on, the Advisor also sends the load balancer updated information about weights and status at least every update interval, if new information is available. Consult the load balancer documentation to determine whether this setting is supported.

The TRUST flag indicates that the load balancer allows other system components besides itself to register members with the load balancer. The z/OS Load Balancing Advisor does not currently exploit this feature.

Line 5 of Figure 138 on page 1147 shows all of these flags. For more information on the NOCHANGE, PUSH, and TRUST flags, see z/OS Communications Server: IP System Administrator's Commands.
**MODIFY proname,DISPLAY,LB,INDEX=lbindex**

This command displays details about a particular load balancer, including its registered groups and members. In Figure 139 on page 1148, the line numbers appearing in the left margin are for reference purposes only, and are used in the subtopics following the figure.

Figure 140. Sample output for the MODIFY procname,DISPLAY,LB,INDEX=lbindex command, part 2 of 2

Group flags - BASEWLM, BASEWLM*, and SERVERWLM

The BASEWLM flag indicates that WLM system weight recommendations were configured or specified by default for this group, and are being used to calculate the net weight. The BASEWLM* flag indicates that server-specific WLM recommendations were configured for this group, but WLM system weight recommendations are being used instead. This occurs when at least one of the Agents owning members within the group does not support server-specific WLM recommendations. The SERVERWLM flag indicates that server-specific WLM recommendations are being used to calculate the net weight for each member in the group. Line 7 in Figure 139 on page 1148 shows the BASEWLM flag, line 39 shows the BASEWLM* flag, and line 25 shows the SERVERWLM flag. For more information on the BASEWLM, BASEWLM*, and SERVERWLM flags, see z/OS Communications Server: IP System Administrator's Commands.

Member flags - LBQ and OPQ

The LBQ flag indicates that the load balancer has quiesced the member. For details on what this entails, see “Stopping or resuming workload distribution to particular members (QUIESCE and ENABLE)” on page 1155. Do not confuse this with the OPQ flag, which indicates that the z/OS operator has quiesced the member at the z/OS Agent. In both cases, the member is ineligible for future workloads through the external load balancer. Line 43 in Figure 139 on page 1148 shows the LBQ flag and the OPQ flag. For
more information on the LBQ and OPQ flags, see z/OS Communications Server: IP System Administrator's Commands.

**Member flags - NOTARGETSYS, NOTARGETIP, and NOTARGETAPP**

These flags indicate that the Advisor will advise the load balancer that the member should not currently receive new workload requests because a resource is unavailable. If the IP address in the member is not present on any TCP/IP stack within the sysplex or subplex, NOTARGETSYS is displayed for that member. This flag can also appear if the Agent owning the IP address in the member has lost contact with the Advisor or has yet to be started. There might be rare instances where the load balancer might decide to go ahead and route workload requests to members that have the NOTARGETSYS flag displayed, if it has no better candidates within the group to route workload requests to. If the member represents an application member and the application is not active, NOTARGETAPP is displayed for that member. If the member is a system member and the IP address is unusable, NOTARGETIP is displayed. This includes distributed VIPAs (DVIPAs), deprecated IPv6 addresses, and unavailable IPv6 addresses. If you ever see the NOTARGETIP flag, you should update the IP address in the member at the load balancer. If application members are coded with any of these addresses, you will always see NOTARGETAPP displayed for these members. Line 19 in Figure 139 on page 1148 shows the NOTARGETSYS flag, line 23 shows the NOTARGETIP flag, and line 47 shows the NOTARGETAPP flag. For more information on the NOTARGETSYS, NOTARGETIP, and NOTARGETAPP flags, see z/OS Communications Server: IP System Administrator's Commands.

**Member flag - NODATA**

This flag is transient and indicates that not enough time has elapsed for the reporting Agent to calculate a Communications Server weight for the member. Therefore, only the WLM weight is used to calculate the net weight, until such time that the Agent can report a Communications Server weight. Until that time, the CS WEIGHT is displayed as 100. When a Communications Server weight has been calculated and transmitted to the Advisor, the NODATA flag is turned off. This flag appears when new members are registered by the load balancer, when the target application that the member represents first becomes active, or shortly after a target application has been moved within the sysplex or subplex. Line 51 in Figure 139 on page 1148 shows the NODATA flag. For more information on the NODATA flag, see z/OS Communications Server: IP System Administrator's Commands.
**Member field - AVAIL**

This field is always displayed for each registered member, and has a value of YES or NO. YES indicates that the member is available for workload request distribution. NO indicates that the member is not available for workload request distribution. For the member to be available for workload request distribution, the target application must be active (if the member represents an application member) on a TCP/IP stack that has not had eventual action message EZD1973E issued by sysplex problem detection and recovery, an Agent must be active on the target system and connected to the Advisor, and the member must not be quiesced by the z/OS operator or by the load balancer. Line 9 in Figure 139 on page 1148 shows an example of the AVAIL field set to YES, and line 17 shows an example of the AVAIL field set to NO. For more information on the AVAIL field, see z/OS Communications Server: IP System Administrator’s Commands.

**Member field - NET WEIGHT**

This field is always present for each registered member, and is the only weight that the load balancer actually receives. It is calculated by applying the Communications Server weight as a percentage of the WLM weight, and then the weight is normalized within its group. Normalization involves reducing the weight values while largely preserving the ratios between the weights. Normalization is performed within a group only if there is more than one available member within the group. Net weights can be in the range 0 – 64. A higher net weight means that member is capable of receiving more work than a member within the same group that has a lower weight. There are certain situations where the net weight can be 0 when neither the WLM weight or the Communications Server weight is 0. This can happen if the member has been quiesced by the z/OS operator or the load balancer. Conversely, there is one case where the WLM weight or the Communications Server weight can be zero, but the net weight is nonzero. This can happen if the net weight of every member in the group calculates to zero, and at least one member of the group is available. In this case, the net weights of all of the available members in the group are changed to 1 to force round-robin distribution among the members in the group, rather than to stop sending new workloads to the group entirely. Line 10 in Figure 139 on page 1148 shows an example of the NET WEIGHT field set to a nonzero value, while line 18 shows an example of the field set to zero. For more information about the NET WEIGHT field, see z/OS Communications Server: IP System Administrator’s Commands.
Member field - WLM WEIGHT

This field is always present for each registered member, and represents the desirability of the system owning the member, relative to the other systems in the sysplex or subplex (system weight), or a measure of how well the individual application is meeting its WLM policies (server-specific weight). Like the Communications Server weight and net weight, a higher value means it is more desirable. WLM weights can be in the range 0 – 64. The WLM weight is used as a key component of the net weight. The WLM weight is the composite weight, and is the sum of the modified CP, zAAP, and zIIP weights displayed on the next line. Line 10 in Figure 139 on page 1148 is one of many lines that contain the WLM WEIGHT field, and Lines 10a and 10b are some of the many lines that contain the modified CP, zAAP, and zIIP weights described in Table 63 on page 1152.

Table 63. WLM WEIGHT - CP, zAAP, and zIIP fields

<table>
<thead>
<tr>
<th>Processor</th>
<th>DISTMETHOD BASEWLM</th>
<th>DISTMETHOD SERVERWLM</th>
</tr>

<td>The first value is the WLM server-specific zIIP recommendation. This is the amount of displaceable zIIP capacity, based on the importance (as defined by the WLM policy) of the application's workload, as compared to the other target systems. The second value is the first value modified by the proportion of zIIP capacity that is currently being consumed by the application's workload, as compared to the other processors (general CPU and zAAP).</td>
</tr>
</tbody>
</table>

Restriction: This information is available to be displayed only if no systems in the sysplex are prior to z/OS V1R9. If any systems in the sysplex are not at this release level, only CP weights are considered when determining a composite weight recommendation.
For more information about the WLM WEIGHT field, see z/OS Communications Server: IP System Administrator's Commands.

**Member field - CS WEIGHT**

This CS WEIGHT field is always present for each registered member, and represents the health of the server with respect to its ability to satisfy recent requests. As with the WLM weight and the net weight, the higher the value the better the health. The Communications Server weight can range from 0 to 100, and is used as a component of the net weight. Line 10 in Figure 139 on page 1148 is one of many lines that contains the CS WEIGHT field. For more information on the CS WEIGHT field, see z/OS Communications Server: IP System Administrator's Commands.

**Member field - ABNORM**

This field is displayed if the GROUP FLAGS field indicates that server-specific (SERVERWLM) WLM recommendations are being used. The ABNORM value is a nonzero value if the server application is experiencing conditions in which transactions are completing abnormally, and represents a rate of abnormal transaction completions per 1000 total transaction completions. It is applicable only for target applications that act as Subsystem Work Managers, reporting transaction status using Workload Management Services, such as IWMRPT. For example, the value of 200 in this example (see Line 28c in Figure 139 on page 1148) indicates that 20% of all transactions processed by the server application are completing abnormally. Under normal conditions or if the server is not providing this information to WLM, this value is 0.

A nonzero value indicates that the server application has reported abnormal transaction completions to WLM and that WLM has reduced the server-specific recommendation for this server instance. The higher the value of this field, the greater the reduction in the recommendation provided by WLM. For more information regarding the conditions leading to abnormal transaction completions for a given server application, see the documentation provided by the server application.

**Restriction:** Although WLM uses the abnormal transaction completion rate provided by the application to reduce the server-specific recommendation, this information is available for display on an Advisor only if the Load Balancing Agents and the Advisor are running on a z/OS V1R8 system. A z/OS V1R7 Load Balancing Agent does not provide this information to the Load Balancing Advisor. In this situation, a z/OS V1R8 Advisor shows a normal abnormal transaction completion rate of 0, even if WLM is reducing the server-specific recommendation because of a nonzero abnormal transaction completion rate reported from the application.

**Member field - HEALTH**

This field is displayed if the GROUP FLAGS field indicates that server-specific (SERVERWLM) WLM recommendations are being used. This health indicator is available only for applications that provide this information to WLM using the IWM4HLTH or IWMSRSRG services, and it indicates the general health for an application or subsystem. Under normal circumstances, or if the server is not providing this information to WLM, the value of this field is 100, meaning the server is 100% healthy.

Any value less than 100 indicates that the server is experiencing problem conditions that are preventing it from processing new work requests successfully, which causes WLM to reduce the server-specific recommendation for this server instance. The lower the value of this field, the greater the reduction in the recommendation provided by WLM.

**Restriction:** Although WLM uses the health indicator provided by the application to reduce the server-specific recommendation, this information is available for display on an Advisor only if the Load Balancing Agents and the Advisor are running on a z/OS V1R8 system. A z/OS V1R7 Load Balancing Agent does not provide this information to the Load Balancing Advisor. In this situation, a z/OS V1R8 Advisor shows a normal health indicator of 100, even if WLM is reducing the server-specific recommendation because of an abnormal health indication from the application.

**Member field - ProcType**

Indicates that CP, zAAP, and zIIP proportions were configured. These proportions are applied against the processor weights to determine the composite BASEWLM weight. For a description of the CP, zAAP, and
zIIP fields for ProcType, see Table 61 on page 1143. Lines 54 and 54a in Figure 139 on page 1148 contain these fields.

**MODIFY procname,DISPLAY,MEMBERS,DETAIL**

This command displays details about members that are owned by the Agent. In Figure 141 on page 1154, the line numbers appearing in the left margin are for reference purposes only, and are used in the subtopics following the figure. For information about every field displayed by the Agent MODIFY command, see z/OS Communications Server: IP System Administrator's Commands.

Figure 141. Sample output for the MODIFY procname,DISPLAY,MEMBERS,DETAIL command

**Member flag - ANY**

The ANY flag means that the application represented by the port in the member is bound to INADDR_ANY or the IPv6 unspecified address (in6addr_any). This means that in an INET (one TCP/IP stack) environment, any externally available IP address owned by that TCP/IP stack might be used to reach the target application, not just the IP address coded in this member. Therefore, there is the potential that multiple members might exist in the load balancer or other load balancers that actually represent the same application, if members were coded with the same port, protocol, and an IP address owned by the same TCP/IP stack. You need to be aware of this if you want to issue operator commands to quiesce that application. If this were the case, quiescing the application at the port level, but specifying the individual IP address of the member, might not quiesce all new workload requests to that application. Quieting the application at the port level without specifying an IP address would be required to accomplish that task. If the application is running in a CINET (multiple TCP/IP stack) environment, any externally available IP address on the z/OS system can be used to reach the target application, unless the application has stack affinity. If the application has stack affinity, the Advisor indicates the member is available only if the IP address coded in the member belongs to the TCP/IP stack that the application has affinity to. Line 18 in Figure 141 on page 1154 shows an example of this flag. For more information on the ANY flag, see z/OS Communications Server: IP System Administrator's Commands.

**Member flag - V6**

The V6 flag indicates that the application that the member refers to has set the IPV6_V6ONLY socket option. This socket option disallows connections to the server application using an IPv4 address as the destination IP address when the server application has bound to the IPv6 unspecified address (in6addr_any). If a member is coded with an IPv4 address and intends to represent an application that has the IPV6_V6ONLY socket option set, the member will not be available for workload balancing and the V6 flag is displayed for this member. Conversely, for any member that represents this target application and is coded with an IPv6 address that can be used to reach the target application, the member will be...
available for workload balancing and the V6 flag is displayed. Line 22 in Figure 141 on page 1154 shows an example of this flag. For more information on the V6 flag, see z/OS Communications Server: IP System Administrator’s Commands.

**Stopping or resuming workload distribution to particular members (QUIESCE and ENABLE)**

At least one and possibly two methods exist to stop sending new workload requests to particular members, referred to as quiescing. Quiescing does not disrupt existing connections with the target applications, but does prevent new workload requests from being distributed to those members from load balancers. Requests sent directly to applications that do not go through the load balancer are unaffected by quiescing. Quiescing certain members can be useful for a planned outage of a particular system in the sysplex, a particular TCP/IP stack, a particular application, or a homogeneous group of applications, such as all HTTP servers. The first method of quiescing is done using the MODIFY procname,QUIESCE operator command available at each Agent. The second potential method is through the load balancer administrator, if the load balancer implementation supports this function. Only the MODIFY procname,QUIESCE command is described in detail in this topic.

The MODIFY procname,QUIESCE command is available only on the Agents, because they own the IP addresses that belong to TCP/IP stacks on that z/OS system. Therefore, the scope of the quiesce operation cannot affect members that are not owned by the Agent that is issuing the command.

There are three major scopes or target options for the MODIFY procname,QUIESCE command:

- **SYSTEM**
  
  Every member owned on that z/OS system can be quiesced
- **TCPNAME=tcpname**
  
  Every member on one of the Agent’s TCP/IP stacks can be quiesced
- **PORT=portnum**
  
  All members using a particular port can be quiesced

The last target option, quiescing by port, enables you to refine the quiesce to an individual member instead of quiescing all members using the port. For more information on how to specify individual members using the Agent’s MODIFY procname,QUIESCE command, see z/OS Communications Server: IP System Administrator’s Commands.

When ready for new workloads, use the MODIFY procname,ENABLE command to make the quiesced members available again. Like the quiesce command, this command is only an Agent command, and also has the same target options as the quiesce command.

The quiesce and enable commands are hierarchical. The system level (SYSTEM target option) is at the top of the hierarchy, the stack level (TCPNAME=tcpname target option) is the next highest, and the member level (PORT=portnum target option) is the lowest.

**Rules:**

- In the quiesce and enable hierarchy, a member quiesced at one level of the hierarchy cannot be enabled at a lower or higher level of the hierarchy. For example, if the MODIFY procname,QUIESCE,TCPNAME=tcpname command has been issued, a MODIFY procname,ENABLE,SYSTEM command or a MODIFY procname,ENABLE,PORT=portnum command will not be accepted.
- An enable command must be issued at the same level of the hierarchy as the last quiesce command that affected the member.
- When a member has been quiesced at one level of the hierarchy, it can be quiesced at a higher level of the hierarchy. This promotes the quiesce level of the member from the lower hierarchy level to the higher hierarchy level, and any history of it being quiesced at the lower level of the hierarchy is erased. When subsequently issuing an enable command in these circumstances, the enable command must be issued at the higher, promoted level of the hierarchy. For example, if member A was quiesced at the port level, a subsequent command to quiesce all members of the TCP/IP stack would be accepted.
Furthermore, only a subsequent enable command at the TCP/IP stack level would be accepted to re-enable the member.

Table 64 on page 1156 shows which quiesce and enable commands are valid for a member after a previous quiesce command has affected that same member. A dot at the intersection of the prior command column and the current command row indicates that the current command would be valid for that member. Absence of a dot indicates that the current command would not be valid after the prior command had affected that member.

<table>

<td>ENABLE,PORT=</td>
<td>●</td>
<td></td>
</tr>
</tbody>
</table>

**Rules:**

- A quiesce command is rejected if any member it applies to has already been quiesced by a command at a higher level of the hierarchy. For example, if you are running in a CINET configuration and you quiesce all members under stack A, which includes a member on stack A that used port 80, you cannot subsequently issue a quiesce command at the port level hoping to quiesce members using port 80 on stacks B and C, because the member on stack A that used that port was already quiesced at the stack level. Because the command would fail for one member, the entire command fails for all members.

- Quiesce commands at the system and stack level apply to currently registered members and also members that are registered in the future, provided that the IP addresses of those future members are owned by the Agent that issued the command. For quiesce commands issued at the stack level, the specified stack must exist at the time the command is issued.

- Quiesce commands at the port level can apply to members registered in the future, if a member currently exists at that port number. For example, if a member is registered by one load balancer at port 80 and the Agent operator quiesces all members at port 80, and then another load balancer registers that same member (same IP address, port, and protocol), the newly registered member would inherit the quiesce performed at the port level.

When a member represents a shareport group (that is, multiple server application instances sharing the same TCP port on the same TCP/IP stack), members cannot be defined to distinguish between the individual server application instances. That is, the combination of the IP address, port, and protocol represents all of the applications sharing the port. Therefore, you cannot selectively quiesce workload requests to only some of the applications sharing the port. Consequently, if you quiesce a member that represents a shareport group, all of the application instances in the group are quiesced.

If an Agent is stopped or fails and is restarted, the quiesce states of any members it might have previously owned are lost. If this occurs, reenter the appropriate quiesce commands to regain the quiesce states that existed during the previous instance of the Agent.

If a member is moved from one system in a sysplex to another using sysplex functions such as VIPA backup, the quiesce state does not move with it. For example, if quiesced member A is using IP address 1.1.1.1 on system X and system X fails, IP address 1.1.1.1 could be moved to system Y. Member A would no longer be quiesced on the new system and, assuming that the application that member A is assigned to is available and active on system Y, new workload requests would be distributed to this application.
If you plan to take a sysplex system out of service, simply stopping the Agent running on that system is not always a wise alternative to issuing a system-level quiesce command on that system’s Agent. If an Agent is simply shut down, there are rare cases where a load balancer might choose to continue routing new workload requests to the applications on that system.

### z/OS Load Balancing Advisor configuration example

This topic includes a specific configuration example of the z/OS Load Balancing Advisor, two Load Balancing Agents, and some customization of PROFILE.TCPIP considerations.

In this example, as shown in Figure 142 on page 1157, load balancer LB1 distributes workload requests to two z/OS systems in a sysplex, SYSA and SYSB. SYSA is a CINET configuration with two TCP/IP stacks. SYSB is an INET configuration with one TCP/IP stack. The load balancer is connected to a LAN that also connects to each target TCP/IP stack in the sysplex, including the TCP/IP stack where the Advisor is running. All addresses in this example are IPv4, but the Advisor and Agents are enabled for IPv6.

This example configuration does not use subplexing or AT-TLS.

---

**Figure 142. z/OS Load Balancing Advisor configuration example**

### Load balancer configuration details

The load balancer distributes two types of workload requests in this example, FTP and HTTP traffic, both of which use the TCP protocol. (Keep in mind that UDP workload requests can also be distributed if wanted.) On SYSA, one FTP server is running, which is shared as a generic server between the two TCP/IP stacks.
stacks. Also, on SYSA, an HTTP server is bound to stack S1. On SYSB, an FTP and HTTP server are running.

The load balancer must be configured with the IP address and port of the Advisor's load balancing connection socket. In this example, the TCP/IP stack on SYSB has defined 10.1.5.1 as a dynamic VIPA. In addition, this same address and port is defined to the Advisor on the lb_connection_v4 statement in the Advisor's configuration file. The load balancer also uses one of its interfaces to communicate with the Advisor. The IP address assigned to this interface must be coded in the Advisor's lb_id_list statement. In this example, the load balancer uses the interface assigned to the address 10.1.10.11. For information on how to determine which interface the load balancer will use to communicate with the Advisor, consult the specific load balancer documentation.

The load balancer advertises its cluster IP address, 10.2.1.21, so that clients that want to connect to specific applications in the sysplex will connect to this cluster IP address as a proxy. After the connection reaches the load balancer, to determine the actual target of the request, the load balancer consults the information that the Advisor has provided as well as possibly examining the content of the packet. The load balancer might substitute the target IP address in the packet header with the IP address of the member that is best suited to receive the new workload requests, or forward the packet as is using the appropriate MAC address. For example, if a connection request came to the load balancer (10.2.1.21) for port 21 using protocol TCP, the load balancer would forward the packet to either 10.1.10.22, 10.1.10.3, or 10.1.10.1, depending upon which member is the better candidate at that point in time.

To distribute FTP workload requests to the sysplex, a group called FtpServerFarm is defined to the load balancer. The load balancer maps the cluster IP address, 10.2.1.21, port 21, and protocol TCP to this group. In other words, if the load balancer receives a TCP connection with destination 10.2.1.21, port 21, it consults this group to find a member to which it can forward the connection. Within this group are three members that can handle FTP connections, representing target applications within the sysplex. One target can be reached at 10.1.10.22 on port 21, the second at 10.1.10.3 on port 21, and the third at 10.1.10.1 on port 21. The target applications represented by these members do not necessarily all have to be available at all times. The load balancer avoids trying to forward connections to target applications that are not currently available. Therefore, the list of target applications represented by the members in the group should be the entire set of possible members that could handle this workload, now or in the foreseeable future.

To distribute HTTP workload requests to the sysplex, a group called WebSvrFrm is defined to the load balancer. The load balancer maps the cluster IP address, 10.2.1.21, port 80, and protocol TCP to this group. In other words, if the load balancer receives a TCP connection with destination 10.2.1.21, port 80, it consults this group to find a member to which it can forward the connection. Within this group are two members that can handle HTTP connections, representing target applications within the sysplex. One target can be reached at 10.1.10.22 on port 80, and the second can be reached at 10.1.10.1 on port 80.

**Advisor configuration details**

There are two aspects of Advisor configuration, the Advisor configuration file itself, and the underlying PROFILE.TCPIP changes that go along with the remainder of the z/OS Load Balancing Advisor system configuration.

The following example is the Advisor configuration file:

```plaintext
debug_level 7                      # Error, Warning, Events-- the default
update_interval 60                 # Agents update every minute-- the default
wlm serverwlm                     # Request server-specific WLM weights
port_list
  {                              
    21   wlm basewlm             # Use system WLM weights for FTP
  }
lb_connection_v4 10.1.5.1..3860   # DVIPA load balancer connects to
lb_id_list
  {                              
    10.1.10.11                   # Load balancer's SASP client interface
  }
```

1158 z/OS Communications Server: IP Configuration Guide
In this example Advisor configuration file, the debug level is set to 7 in the optional debug_level statement. The value of 7 is the default value, so this statement is redundant but is shown for completeness. At the default level of 7, messages are written to the log if they are at error, warning, or event level. Messages at other debug levels, such as info or debug, are not written to the log file.

The optional update_interval statement is set to 60 seconds, which is also the default. This means that each Agent updates the Advisor with new information every minute. For some load balancer implementations, depending upon load balancer configuration, it might also determine how often the load balancer is updated with new information from the Advisor.

The wlm statement specifies the default WLM recommendation type to be used for all groups when calculating the net weights. The value of severwlm indicates that server-specific WLM recommendations will be requested of each Agent, unless overridden by the port_list statement (see next paragraph). Although server-specific WLM is the WLM recommendation type to be used for all groups except FTP in this example, there is still a possibility that WLM system weights might have to be used for some or all groups. For further details on the serverwlm value on the wlm statement, see z/OS Communications Server: IP Configuration Reference.

The port_list statement contains one port number, 21. The wlm keyword indicates that the WLM recommendation type will be overridden for all members using port 21 (FTP), to use WLM system weights rather than server-specific WLM weights when calculating the net weight. Multiple port numbers can appear in the port_list statement on separate lines, if you want to use WLM system weights for other groups of members.

The lb_connection_v4 statement includes DVIPA 10.1.5.1 and port 3860 (the default) as the address and port that load balancers use to connect to the Advisor. The load balancer specifies this address and port when defining the location of the Advisor.

The lb_id_list statement contains the address 10.1.10.11, which is the source IP address of the load balancer when the load balancer connects to the Advisor as a SASP client. If more than one load balancer is used to distribute workload requests to the sysplex, each load balancer needs to be represented in this statement list.

The agent_connection_port statement specifies that port 8100 is used to listen for connections from Agents in the sysplex. This same port appears on each Agent's advisor_id statement. This port is reserved on the TCP/IP stack that the Advisor runs on, and on any TCP/IP stacks that the Advisor could be moved to in the event of failure. Using this port, the Advisor opens a listening socket on the IPv4 or IPv6 unspecified address (0.0.0.0 or ::, respectively), depending upon the TCP/IP stack's IPv6 capability.

The agent_id_list statement contains the source IP address and port of each Agent in the sysplex. The 10.1.1.1 address and the associated port of 8000 represent the source IP address and port that the Agent on SYSB uses to communicate with the Advisor. This same address and port combination appears on the agent_connection statement in the Agent's configuration file on SYSB. The 10.1.5.22 address and the associated port of 8000 represent the source IP address and port that the Agent on SYSA uses to communicate with the Advisor. This same address and port combination appears on the agent_connection statement in the Agent's configuration file on SYSA.

**Agent configuration file on SYSB**

The following example is the Agent configuration file on SYSB:

```
depth_level 7                  # Error, Warning, Events
advisor_id 10.1.5.1..8100     # DVIPA of Advisor Agent connects to
```
In this example Agent configuration file for SYSB, the debug level is set to 7 in the optional debug_level statement. The debug_level statement for an Agent functions similarly to the way it functions for the Advisor.

The advisor_id statement is configured with the address 10.1.5.1 and port 8100. This tells the Agent which address and port the Advisor is using for connections from Agents. The address 10.1.5.1 is configured as a DVIPA on the Advisor's TCP/IP stack. The port of 8100 also appears on the agent_connection_port statement in the Advisor's configuration file, and is also reserved on the Advisor's TCP/IP stack.

The host_connection statement is configured with the address 10.1.1.1 and port 8000. This is the source IP address and port that this Agent uses when connecting to the Advisor. The address is defined as a static VIPA on the TCP/IP stack that the Agent will run on. This address and port must also be specified in the agent_id_list statement in the Advisor's configuration file. The port, 8000, is also reserved in PROFILE.TCPIP of stack S1 on system SYSB.

**Agent configuration file on SYSA**

The following example is the Agent configuration file on SYSA:

```
debug_level 7 # Error, Warning, Events
advisor_id 10.1.5.1..8100 # DVIPA of Advisor Agent connects to
host_connection 10.1.5.22..8000 # Source DVIPA and port this Agent
# uses to connect to the Advisor
```

This Agent configuration file is for the Agent running on SYSA. The debug_level and advisor_id statements are identical to the Agent configuration file on SYSB. The host_connection statement is configured with the address 10.1.5.22 and port 8000. This is the source IP address and port that this Agent uses when connecting to the Advisor. This address and port must also be specified on the agent_id_list statement in the Advisor's configuration file. The port, 8000, is also reserved in PROFILE.TCPIP of stack S1 and S2 on system SYSA. This address is defined as a dynamic VIPA on both TCP/IP stacks on SYSA, in the event that one of the TCP/IP stacks fails.

**Customization of PROFILE.TCPIP**

Each TCP/IP profile in the sysplex must be updated to accommodate the z/OS Load Balancing Advisor.

The updated portion of PROFILE.TCPIP for stack S1 on system SYSB follows:

```
VIPADYNAMIC
;Address LB & Agents use to reach Advisor fall into this subnet
VIPARANGE DEFINE 255.255.255.0 10.1.5.0
ENDVIPADYNAMIC

DEVICE VIPA41 VIRTUAL 0 ; Static VIPA for Agent's source address
  LINK LVIPA41 VIRTUAL 0 VIPA41
  HOME 10.1.1.1 LVIPA41

PORT
  3860 TCP LBADV ; SASP Workload Advisor (LB connections)
  8100 TCP LBADV ; SASP Workload Advisor (Agent connections)
  8000 TCP LBAGENT ; SASP Workload Agent (Advisor connection)
```

In this example, the address 10.1.5.1 would be within the subnetwork that has been reserved for dynamic VIPAs in the VIPARANGE statement. The load balancer and the Agents use this address to reach the Advisor. Using a dynamic VIPA (DVIPA) facilitates the movement of the Advisor to another TCP/IP stack in the event of failure. This address is defined in the lb_connection_v4 statement in the Advisor's configuration file, in the load balancer as the location of the Advisor [known generically as the SASP Global Workload Manager (GWM)], and on the advisor_id statement in each of the Agent's configuration files.
The address 10.1.1.1 is a static VIPA. The Agent on this system uses this address as its source IP address. Because SYSB is a single stack system (INET), a static VIPA is sufficient. If this were a CINET system like SYSA, a DVIPA would be best. This address appears on the agent_id_list statement in the Advisor’s configuration file, as well as on the agent_connection statement in the Agent’s configuration file on SYSB.

The ports used for the Advisor and Agent are reserved, as advised. Port 3860 is reserved for the Advisor and is used to communicate with load balancers. This port appears on the lb_connection_v4 statement in the Advisor’s configuration file. Port 8100 is also reserved for the Advisor, and is the port that the Agents use to connect to the Advisor. This port appears on the agent_connection_port statement in the Advisor’s configuration file, as well as on the advisor_id statement in each of the Agents’ configuration files. Port 8000 is reserved for the Agent on this system and is used as the source port for the connection with the Advisor. This port appears on the agent_id_list statement in the Advisor’s configuration file, as well as on the agent_connection statement in the Agent’s configuration file on this system.

The updated portion of PROFILE.TCPIP for stack S1 on system SYSA follows:

```
VIPADYNAMIC
 ;Address Agent uses as source will fall into this subnet
 VIPARANGE DEFINE 255.255.255.0 10.1.5.0
ENDVIPADYNAMIC

PORT
  3860 TCP LBADV ; SASP Workload Advisor LB connections,
                  ; in case Advisor is moved to this stack
  8100 TCP LBADV ; SASP Workload Advisor Agent connections,
                  ; in case Advisor is moved to this stack
  8000 TCP LBAGENT ; SASP Workload Agent Advisor connection
```

In Figure 142 on page 1157, the DVIPA that the Agent uses as a source IP address on this system is shown belonging to stack S1. It could just as easily belong to stack S2, but for the purposes of this example the DVIPA belongs to stack S1.

In this updated portion of PROFILE.TCPIP, the address that the Agent uses as a source address when connecting to the Advisor, 10.1.5.22, is within the subnetwork that has been reserved for dynamic VIPAs on the VIPARANGE statement. Using a dynamic VIPA (DVIPA) facilitates the movement of the Agent to another TCP/IP stack on the same system in the event of failure. This address is defined on the host_connection statement in this Agent’s configuration file, and in the agent_id_list statement in the Advisor’s configuration file. The DVIPA that the Advisor would use, should the Advisor be moved to this stack, would also fall within this subnetwork.

The port that is used for the Agent is reserved, as advised. Additionally, ports that the Advisor would use if it were to be moved to this TCP/IP stack are also reserved.

The updated portion of PROFILE.TCPIP for stack S2 on system SYSA follows:

```
VIPADYNAMIC
 ;Address Agent uses as source will fall into this subnet
 VIPARANGE DEFINE 255.255.255.0 10.1.5.0
ENDVIPADYNAMIC

PORT
  3860 TCP LBADV ; SASP Workload Advisor LB connections,
                  ; in case Advisor is moved to this stack
  8100 TCP LBADV ; SASP Workload Advisor Agent connections,
                  ; in case Advisor is moved to this stack
  8000 TCP LBAGENT ; SASP Workload Agent Advisor connection
```

This updated portion of the TCP/IP profile is identical to that of stack S1 on SYSA. This TCP/IP stack is capable of supporting the Advisor and the Agent running on this z/OS system, should it be necessary to move either to this TCP/IP stack.
Example displays

The following display is from the SYSB Advisor:

Chapter 22. Automated domain name registration

The automated domain name registration (ADNR) application is a function that dynamically updates name servers with information about sysplex resources in near real time. As resources in the sysplex become available, Domain Name System (DNS) resource records are added to one or more name servers. As those resources become unavailable, the corresponding DNS resource records are removed from the name server. Clients that connect to sysplex resources using DNS names have a greater likelihood of connecting to an available resource in the sysplex. ADNR also removes the administrative burden of manually configuring and updating a name server to represent sysplex resources.

The DNS names managed by ADNR can be application-specific names. All instances of the same application within the sysplex can be represented by the same DNS name. Clients can therefore use one DNS name to connect to any available application instance within the sysplex. ADNR can also manage DNS names that map to specific application instances. These names are used when a client wants affinity to one particular application instance.

In addition to application-specific names, ADNR can also manage DNS names that generically represent the entire sysplex, as well as names that represent individual systems within the sysplex.

How connections are distributed within the sysplex is determined by name server and ADNR configuration. Typically, connections are fairly evenly distributed among the available application instances over time. Connections are not load balanced within the sysplex, as they are with load balancing solutions such as sysplex distributor and the z/OS Load Balancing Advisor.

ADNR supports both IPv4 and IPv6 addresses.

System overview

Figure 143 on page 1165 shows a z/OS sysplex containing four systems, a name server external to the sysplex, a name server in the sysplex, and several clients in the network. The z/OS Load Balancing Advisor and ADNR are running on one of the systems in the sysplex. An instance of the z/OS Load Balancing Agent is active on three of the sysplex systems. Three instances of a server application are active within the sysplex.

Figure 143. System overview
ADNR is configured with information about sysplex resources to which you want to assign DNS names. These resources are configured on a group basis. For example, to have ADNR manage DNS names in a name server for a sysplex containing several instances of a CICS listener application, all potential CICS listener instances for a given port in the sysplex are defined under the same group in the ADNR configuration file.

ADNR registers its configured information about sysplex resources with a z/OS Load Balancing Advisor application. The Advisor application disseminates this information to the z/OS Load Balancing Agents (Agents), which report back to the Advisor about the availability of the resources registered by ADNR. The Advisor then reports back to ADNR about which of its registered resources are active and which are not. The Advisor subsequently reports to ADNR any changes in the availability of those resources.

For each group of resources that the Advisor reports as available, ADNR adds a DNS name to the name server that represents the entire group of resources in that group, and maps that name to the IP addresses of the available resources in that group. Continuing with the CICS listener example, the IP address of each active CICS listener application is mapped to the name representing the entire group of CICS listener applications. The IP address of each inactive CICS application is not mapped to that DNS name. Clients then connect to their application using the name that ADNR added to the name server. The address or addresses returned to the client’s resolver reflect only active application instances. Thus, the client can use one DNS name to connect to any active instance of an application. As application instances become unavailable, the addresses of those unavailable application instances are disassociated from that DNS name in the name server. If all application instances in that group become unavailable, the DNS name representing that group of applications is removed from the name server.

You can also configure ADNR to update the name server with the names of individual server instances, which map to IP addresses that can be used to reach those server instances as those server instances become available. Thus, if a client needs to connect to a specific server instance, that name can be used to make the connection. As each individual server instance becomes unavailable, the DNS name representing the unavailable server instance is removed from the name server.

The name servers that ADNR manages must support RFC 2136, Dynamic Updates in the Domain Name System (DNS UPDATE). For information about accessing RFCs, see Appendix G, “Related protocol specifications,” on page 1381.

For administrative purposes, it is advantageous to run ADNR within the same sysplex as the resources it manages. Run ADNR in a sysplex so that it can be moved to provide optimal availability. You can reduce network traffic between ADNR and the Advisor by running ADNR on the same system where the Advisor is running. In addition, the possibility of network outages disrupting communication between ADNR and the Advisor is eliminated by this configuration.

Interaction with name servers

The name servers that ADNR manages require a one-time setup. These name servers must be configured as the primary master name servers for the zones managed by ADNR. The name servers must support RFC 2136, Dynamic Updates in the Domain Name System (DNS UPDATE). For information about accessing RFCs, see Appendix G, “Related protocol specifications,” on page 1381.

For more background information about DNS, see “DNS overview” on page 703.

For more information about name server configuration considerations, see “Name server configuration considerations” on page 1179.

Interaction with the z/OS Load Balancing Advisor

The ADNR function is provided by the ADNR application, which uses the z/OS Load Balancing Advisor function.

Requirement: You must configure and deploy the z/OS Load Balancing Advisor and Agent to use ADNR. An external load balancer is not required.

The ADNR application communicates with the Advisor using the Server/Application State Protocol (SASP). In SASP protocol terms, the Advisor is known as a Global Workload Manager (GWM). The terms Advisor
and GWM are used interchangeably. From the GWM’s perspective, the ADNR application appears as a load balancer. Despite its appearance as a load balancer to the GWM, ADNR does not perform load balancing. The z/OS Load Balancing Advisor supplies sysplex resource availability and weight information to what it views as load balancers, including ADNR. ADNR uses the availability information but does not use the weight information.

For more information about this function, see Chapter 21, “z/OS Load Balancing Advisor,” on page 1117.

For more information about z/OS Load Balancing Advisor configuration considerations, see “z/OS Load Balancing Advisor configuration considerations” on page 1178.

Enabling TLS/SSL for ADNR

Consider whether to use AT-TLS for security between ADNR and the z/OS Load Balancing Advisor. AT-TLS provides the ability to authenticate a client, check authorizations, and encrypt data. You must restrict the ability to establish a connection to the Advisor, because sensitive interfaces can be exploited after a connection is accepted by the Load Balancing Advisor. Because ADNR acts as a client to the Load Balancing Advisor SASP port, it must be explicitly authorized to establish its connection to the Load Balancing Advisor.

You can use one or both of the following methods to authorize connection to the z/OS Load Balancing Advisor:

- You can explicitly configure the host_connection_addr keyword on the gwm statement in the ADNR configuration file, and the corresponding lb_id_list statement in the Advisor’s configuration file.
- You can establish policies using the z/OS Policy Agent so that ADNR is required to use AT-TLS.

Although the configuration parameters might be sufficient in certain environments where the Load Balancing Advisor and ADNR are inside a secure network (that is, isolated by a firewall and so on), they might not be sufficient in environments in which the network is not considered to be as secure or in which the need to protect against IP address spoofing attacks is important. For more information about using AT-TLS, see Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1093. For more information about the Advisor, see Chapter 21, “z/OS Load Balancing Advisor,” on page 1117.

Steps for configuring automated domain name registration

The automated domain name registration (ADNR) application dynamically updates name servers with information about sysplex resources. Detail for each step is provided in the corresponding subtopic.

**Procedure**

Perform the following steps to configure the automated domain name registration (ADNR) application.

1. Decide which sysplex resources should be managed by ADNR.
2. Decide on one or more domain names to be managed by ADNR.
3. Decide which name server or name servers are to be managed by ADNR.
4. Configure the selected name servers to be the primary master name servers for the domain names that ADNR is to manage.
5. Delegate the domain names to be managed by ADNR to the selected name servers from the parent domain's name server.
6. Configure the z/OS Load Balancing Advisor (LBA) function.
7. Define security server profiles for ADNR.
8. Configure ADNR to automatically restart in case of application or system failure. (optional)
9. Configure and start syslogd. (optional, but required to have ADNR write log messages and trace data to syslogd)
10. Configure one ADNR application per sysplex.
11. Customize the TCP/IP profiles of the TCP/IP stacks on which ADNR and the LBA applications are to run. (optional)
12. Start the TCP/IP stacks on which ADNR and the LBA applications are to run.
13. Start the z/OS Load Balancing Advisor and Agent.
14. Start the target applications that are to be managed by ADNR.
15. Start the ADNR application.
16. Verify that the ADNR system is functioning correctly. (optional)

Results
These steps are described in detail in the following subtopics.

Step 1: Decide which sysplex resources should be managed by ADNR

ADNR can manage two types of sysplex resources, including server applications and the traditional DNS mappings of host names to IP addresses. Server applications are represented in ADNR as server groups using the server_groups statement. Traditional DNS host name-to-IP address mappings are represented as host groups using the host_groups statement. For more information about server groups and host groups, see “Identifying the sysplex resources to be managed by ADNR” on page 1173.

ADNR can dynamically create application-specific host names in a name server to represent a cluster of equivalent servers in the sysplex. For example, the name ztelnet.mvsplex.mycorp.com can represent all TN3270E Telnet server applications in the sysplex. Any TCP or UDP server application in the sysplex can be managed by ADNR and have application-specific host names dynamically added and removed from a name server to represent active instances of those servers. As server applications become available, ADNR dynamically adds resource records representing those instances to the name servers managed by ADNR. As those server applications or their systems become unavailable, ADNR dynamically deletes resource records representing those instances from the name servers it manages. These types of DNS names can be used to connect to any active instance of a particular type of server. ADNR also dynamically creates and removes application-specific host names that represent individual instances of server applications as they become available and unavailable.

Most IP addresses in the home lists of sysplex hosts can be dynamically added to the name server as traditional DNS name-to-IP address mappings. As IP addresses are removed from a home list (for example, by issuing a VARY TCPIP,OBEYFILE command), the DNS resource records representing those IP addresses are dynamically removed from the ADNR-managed name servers. These types of DNS names can be used to connect to any resource in the sysplex, or on a particular sysplex host without regard to which servers are available on that system, such as when using the ping or traceroute commands.

The IP addresses that are added to DNS by ADNR can be interface addresses, static VIPAs, or dynamic VIPAs (DVIPAs). A small set of addresses cannot be managed by ADNR because of z/OS Load Balancing Advisor restrictions. For more information, see “Step 7: Configure the external load balancers” on page 1138 and the restriction that certain classes of IP addresses must not be coded for members in the load balancer.

You might want to make some sysplex resources visible to some set of clients and not visible to other sets of clients. For example, you might want to add DNS entries to make some sysplex resources visible to intranet clients, but not make the resources visible to Internet clients. There are several ways to accomplish this. Some methods can be accomplished with only name server configuration, others might involve ADNR configuration. For more information, see “Split DNS (views)” on page 1182.

Step 2: Decide on one or more domain names to be managed by ADNR

All resource records added to a name server have a domain suffix related to a name server zone. Typically, an enterprise's domain suffix is something like mycorp.com. Subdomains can exist under a domain, which have the subdomain name added before the parent's domain suffix, such as raleigh.mycorp.com and austin.mycorp.com.
Guideline: Because ADNR should be the only entity updating the zones it manages, ADNR should manage one or more unique sub-zones. For example, if your enterprise has a domain name of mycorp.com, ADNR can be configured to manage resources in a domain called mvsplex.mycorp.com.

The domain suffix of the resource records that ADNR creates is determined by the domain_suffix keyword of the zone keyword of the dns statement in the ADNR configuration file.

Step 3: Decide which name server or name servers are to be managed by ADNR

ADNR can manage name servers that support RFC 2136, Dynamic Updates in the Domain Name System (DNS UPDATE). For information about accessing RFCs, see Appendix G, “Related protocol specifications,” on page 1381.

The name servers that ADNR communicates with can be existing name servers, or name servers you set up exclusively for ADNR. Each name server that ADNR is to communicate with is identified on the dns_id keyword of the dns statement.

You might also want to configure one or more secondary name servers for the ADNR-managed zones. Secondary name servers replicate zone data information from the master name server for those zones. Typically, secondary name servers are configured to avoid a single point of failure if a name server fails, and to reduce network traffic by locating secondary name servers in strategic areas of a network so that name server lookups traverse fewer hops in the network.

ADNR does not communicate directly with secondary name servers. Secondary name servers communicate directly with the master name server by performing zone transfers. Ideally, because of the dynamic nature of the data in the zones that ADNR manages, secondary name servers need to be updated as soon as the master name server is updated by ADNR. Otherwise, the secondary name server contains stale information that does not accurately reflect the current availability of sysplex resources. Some name server implementations can minimize the latency with which secondary name servers are updated from their masters, if they have implemented RFC 1996, A Mechanism for Prompt Notification of Zone Changes (DNS NOTIFY). For information about accessing RFCs, see Appendix G, “Related protocol specifications,” on page 1381.

Step 4: Configure the selected name servers to be the primary master name servers for the domain names that ADNR is to manage

The name servers that ADNR communicates with must be configured as the primary master name servers of the zones that ADNR will manage. For more information and further references about configuring the zones that ADNR is to manage in the name server, see “Initial zone configuration” on page 1179.

Step 5: Delegate the domain names to be managed by ADNR to the selected name servers from the parent domain's name server

Typically, the DNS domains that ADNR manages are subdomains of an existing DNS domain. For resolvers to reliably find resource records in the ADNR-managed subdomains, the ADNR-managed subdomain must be delegated by its parent domain. This enables resolvers to find resource records in the ADNR-managed subdomain if those resolvers are not pointing directly to the ADNR-managed name server. DNS queries from resolvers can follow the DNS delegation tree downward from the root domain, if necessary, and find an authoritative name server for the ADNR-managed subdomain.

Delegating a subdomain from a parent involves updating the parent domain’s zone data file. In the parent's zone data file, an NS record and an associated A or AAAA glue record is added to represent each authoritative name server for the child domain. For example, to delegate the ADNR-managed mvsplex.mycorp.com zone from the mycorp.com zone, the following resource records are added to the zone data file for the mycorp.com zone:

<table>
<thead>
<tr>
<th>Name</th>
<th>Ttl</th>
<th>Type</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>mvsplex</td>
<td>86400</td>
<td>NS</td>
<td>mvsnameserver.mvsplex.mycorp.com.</td>
</tr>
<tr>
<td>networknameserver.mvsplex.mycorp.com.</td>
<td>86400</td>
<td>A</td>
<td>10.5.1.1</td>
</tr>
<tr>
<td>2001:0DB8:0:0:8:800:200C:417A</td>
<td></td>
<td>AAAA</td>
<td>2001:0DB8:0:0:8:800:200C:417A</td>
</tr>
</tbody>
</table>
The example resource records delegate the mvsplex.mycorp.com zone to two authoritative name servers, one of which must be the master name server and the other a secondary name server.

**Step 6: Configure the z/OS Load Balancing Advisor function**

Configuring and running the z/OS Load Balancing Advisor (LBA) function is a corequisite to implementing ADNR. The z/OS Load Balancing Advisor application communicates with ADNR and serves as ADNR's Global Workload Manager (GWM). The z/OS Load Balancing Agents communicate with the Advisor application and supply it, and ultimately ADNR, with information about the availability of the resources that ADNR has registered with the Advisor. Therefore, each system in the sysplex that contains resources that you want ADNR to manage must be running an Agent, and one system in the sysplex must be running an Advisor.

The Advisor views ADNR as a load balancer, although ADNR does not perform load balancing. ADNR merely uses the information to update the name servers based on the resource availability that the Advisor provides. Therefore, to enable ADNR to connect to the Advisor, the source IP address that ADNR uses to connect to the Advisor must be configured in the Advisor’s lb_id_list statement, if AT-TLS is not used. For information about the lb_id_list statement, see *z/OS Communications Server: IP Configuration Reference.*

For complete information about configuring the Advisor and Agents, see “Steps for configuring the z/OS Load Balancing Advisor” on page 1122. While following those steps, you should skip step 10 to start the TCP/IP stacks that the Advisor and Agents will use until completing the TCP/IP profile customization for those stacks, described in “Step 11: Customize the TCP/IP profiles of the TCP/IP stacks on which ADNR and the LBA applications are to run (optional)” on page 1176. You should also skip steps 13 and 14 in those steps, starting the Agents and Advisor, until you reach “Step 13: Start the z/OS Load Balancing Advisor and Agent” on page 1176.

**Step 7: Define security server profiles for ADNR**

Create a USERID profile for ADNR as follows:

```
ADDUSER ADNR DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(nn) -
  HOME('/RDWR_working_directory') PROGRAM('/bin/sh'))
```

ADNR must have read and write access to the directory specified on the HOME keyword. This directory becomes ADNR's working directory. ADNR creates and deletes temporary files in this directory during its operation. The UID value, nn, can be zero or nonzero.

ADNR is a multi-threaded application. If you define an unusually large number of name servers or zones to ADNR, you should check to determine whether the maximum number of threads allowed per process, represented by the THREADSMAX value in BPXPRMxx, is going to be exceeded. The number of threads required for ADNR is determined in the following way: (number of dns statements) + (number of zone keywords within all dns statements) + 3. You can customize the maximum number of threads allowed for ADNR by specifying the THREADSMAX keyword on the ADDUSER command.

The program specified on the user ID assigned to run ADNR must be /bin/sh. For more information about specifying a user program and the ADDUSER command, see *z/OS Security Server RACF Command Language Reference.*

Add ADNR to the STARTED class profile:

```
RDEFINE STARTED ADNR.* STDATA(USER(ADNR))
```

**Steps for granting authority to start ADNR**

Grant explicit authority to all users that can start ADNR, to prevent unauthorized users from starting it. If you do not grant explicit authority, any user able to issue the START command can start ADNR.

**Procedure**

Perform the following steps to grant authority to start ADNR.

---

1170 z/OS Communications Server: IP Configuration Guide
1. Ensure that the OPERCMDS class is active and RAListed, and that RAList processing is enabled:

```sh
SETROPTS CLASSACT(OPERCMDS)
SETROPTS RAList (OPERCMDS)
```

2. Define the following OPERCMDS class profile using a security product like RACF:

```sh
RDEFINE OPERCMDS (MVS.SERVGRM.ADNR) UACC(NONE)
```

3. Grant ADNR access to the OPERCMDS class:

```sh
PERMIT MVS.SERVGRM.ADNR CLASS(OPERCMDS) ACCESS(CONTROL) -
   ID(userid)
```

4. Refresh the OPERCMDS class:

```sh
SETROPTS RAList(OPERCMDS) REFRESH
```

5. See the EZARACF sample in SEZAINST for specific instructions.

All commands that you can issue against ADNR are MODIFY commands, with the exception of the STOP command used to stop ADNR. Therefore, you might also want to limit which users are able to issue MODIFY and STOP commands.

**Step 8: Configure ADNR to automatically restart in case of application or system failure (optional)**

Automatically restarting ADNR minimizes the period of time that name servers do not accurately reflect the status of sysplex resources. This can be accomplished using automation software or by defining an automatic restart manager (ARM) policy. For more information about defining ARM policies, see z/OS MVS Setting Up a Sysplex.

ADNR registers with ARM using the following values:

```sh
ELEMTYPE=SYSTCP/IP
ELEMNAME=EZBADNRelemsuffix
TERMTYPE=ALLTERM
```

The `elemsuffix` value is specified in the arm_element_suffix configuration statement. ADNR registers the element name EZBADNR concatenated with the `elemsuffix` value. If there is no arm_element_suffix statement, the ELEMNAME is EZBADNR. For example, if the following statement is configured:

```sh
arm_element_suffix SYS1
```

ADNR registers ELEMNAME=EZBADNR SYS1.

When ADNR registers with ARM using these values, then if ADNR fails or the system fails, ADNR can be restarted on any system in the sysplex.

An ARM policy or other automation software should be in place to quickly restart the TCP/IP stack that ADNR is running on if the TCP/IP stack fails. ADNR continues to run after its TCP/IP stack fails, and reconnects to its GWM after the TCP/IP stack recovers.

Although this step is optional, performing it provides high availability to your target applications. In the event that ADNR fails, the name servers it manages are no longer updated with sysplex resource availability information. As a result, client connections might fail because the name server might resolve their requests to application instances that are not available, or be unable to resolve DNS requests to any application when active application instances might actually exist. When ADNR is restarted, it again accurately reflects the availability of sysplex resources after its convergence period. The convergence period is twice the interval at which the Advisor normally updates ADNR with new information. The interval is determined by the update_interval statement in the Advisor's configuration file.

**Guidelines:**

- Each ADNR instance should have a unique ARM element name within a sysplex.
• Establish an ARM policy with TCP/IP at a lower level than ADNR, so that TCP/IP is restarted before ADNR is restarted. For more information, see z/OS MVS Setting Up a Sysplex.

• To enable ADNR to continue operating on another TCP/IP stack in a Common INET (CINET) environment in the case of TCP/IP stack failure, or to restart on another system in case of system failure, configure ADNR with a unique application-instance DVIPA. The unique application-instance DVIPA is coded on the host_connection_addr keyword of the gwm statement. For more information about unique application-instance DVIPAs, see “Configuring the unique application-instance scenario” on page 359.

**Rule:** AUTOLOG can be used to start ADNR when the TCP/IP stack is started, but it cannot be used for ADNR recovery. Using AUTOLOG for recovery requires port reservation, but ADNR does not listen on a port. Therefore, ADNR can appear in the TCP/IP AUTOLOG statement, but it cannot appear on the PORT statement. ADNR uses ephemeral ports when connecting to its GWM.

**Requirement:** ADNR does not run using a system key. Therefore, if you are using ARM registration, the started task ID needs to be permitted with UPDATE authority to the associated IXCARM.SYSTCPIP.EZBADNR* profile in the FACILITY class within the SAF product on your system. To enable ADNR to register to ARM, use the following RACF commands to define the profile and grant update access to the user ID that is assigned to start ADNR:

```
RDEFINE FACILITY IXCARM.SYSTCPIP.EZBADNR* UACC(NONE)
PERMIT IXCARM.SYSTCPIP.EZBADNR* CLASS(FACILITY) ID(ADNR) ACCESS(UPDATE)
SETROPTS REFRESH RACLIST(FACILITY)
```

**Restriction:** If ADNR is using IPv6 for the GWM connection, or if ADNR is using IPv6 to connect to a name server, movement of ADNR is limited to those TCP/IP stacks that are enabled and configured for IPv6. For considerations for configuring z/OS for IPv6, see z/OS Communications Server: IPv6 Network and Application Design Guide.

**Step 9: Configure and start syslogd (optional, but required to have ADNR write log messages and trace data to syslogd)**

ADNR writes most log messages and trace data to the syslog daemon (syslogd). A limited number of messages are written to the MVS console, but these are unaffected by syslogd configuration. For ADNR to be able to write log messages and trace data to syslogd, syslogd must be properly configured and started before ADNR is started.

Because you might be running ADNR on the same system as the Advisor, for better readability, you might want to configure syslogd to place Advisor and ADNR log output in separate files. For further information, see “Configuring the syslog daemon” on page 199.

**Step 10: Configure one ADNR application per sysplex**

ADNR reads configuration data from one file, which can exist as a z/OS UNIX file, a PDS or PDSE member, or a sequential data set. If you plan to enable ADNR to move within the sysplex in the case of failure, the ADNR configuration file or data set should be on shared DASD, to make it accessible to all systems in the sysplex if necessary. The ADNR configuration file is specified on the CONFIG DD statement in the ADNR start procedure. A sample start procedure is provided in EZBADNRS in SEZAINST.

The ADNR configuration file serves five basic purposes:

• Identifies the name servers to update and the zones to be updated in those name servers
• Identifies the GWM to connect to and IP address to bind to for communications with the GWM
• Identifies the sysplex resources to be managed by ADNR
• Uniquely identifies the ADNR instance
• Customizes optional statements

A sample ADNR configuration file is provided in EZBADNRC in SEZAINST.

**Tip:** Consistent with the Advisor and Agent configuration terminology, any statement or keyword containing the word connection refers to a local socket, and any statement containing the word id refers to a remote address and possibly a port.
The ADNR configuration file contains statements or keywords that reference other statements or keywords. All such references are made using labels.

**Identifying the name servers to update and the zones to be updated in those name servers**

Use the `dns` statement to identify the location of a name server to be managed by ADNR. This statement has a `dns_id` keyword that contains the IP address of a name server and optionally a port. You can code multiple `dns` statements.

**Rule:** In general, for data integrity reasons, multiple `dns` statements should not refer to the same name server. However, if you are configuring ADNR to work with a split DNS configuration, this is acceptable. For more information, see “Split DNS (views)” on page 1182.

The `dns` statement also contains one or more zone keywords that identify a zone in the name server to be updated. The domain suffix specified on the `domain_suffix` parameter must represent a zone previously configured in the name server that is being updated. For more information, see “Initial zone configuration” on page 1179.

The zone keyword contains three optional parameters, `update_key`, `transfer_key`, and `ttl`.

- The `update_key` parameter and the `transfer_key` parameter enable the use of digital signatures on requests sent from ADNR to the name server. The digital signatures provide a way for the name server to authenticate ADNR as a client that is authorized to update the name server and to receive zone transfer information. These digital signatures are called transaction signatures (TSIG). Use of TSIGs requires coordination between ADNR configuration and name server configuration. For more information about TSIG security, see “Authorizing dynamic updates” on page 1180 and “Authorizing zone transfers” on page 1181.
- The `ttl` parameter determines how long resolvers and non-authoritative name servers keep ADNR-managed resource records cached. For more information, see “Near real-time availability information of sysplex resources” on page 1178.

**Identifying the GWM to connect to and IP address to bind to for communications with the GWM**

Specify the location of the GWM on the `gwm_id` keyword of the `gwm` statement. This keyword contains an IP address and optionally a port that the GWM uses to listen for connections from load balancers. From the GWM’s point of view, ADNR is considered a load balancer.

Specify the IP address that ADNR will bind to for communications with the GWM on the `host_connection_addr` keyword of the `gwm` statement. If you are using AT-TLS, the `host_connection_addr` keyword is optional.

**Rules:**

- The IP address specified on the `gwm_id` keyword of the `gwm` statement must match the address specified on the `lb_connection_v4` statement or the `lb_connection_v6` statement in the Advisor configuration file.
- The port specified on the `gwm_id` keyword of the `gwm` statement must match the port specified on the Advisor’s `lb_connection_v4` or `lb_connection_v6` statement, depending upon whether you specify an IPv4 or IPv6 address, respectively, on the `gwm_id` keyword.
- If an IPv4 address is specified on the `gwm_id` keyword of the `gwm` statement, an IPv4 address must be specified on the `host_connection_addr` keyword of the `gwm` statement. Similarly, if an IPv6 address is specified on the `gwm_id` keyword of the `gwm` statement, an IPv6 address must be specified on the `host_connection_addr` keyword of the `gwm` statement.

**Guideline:** For high availability, use a unique application-instance DVIPA for the address on the `host_connection_addr` keyword. This enables ADNR to be moved to another TCP/IP stack or another system in the event of TCP/IP stack or system failure.

**Identifying the sysplex resources to be managed by ADNR**

Specify which sysplex resources should be managed by ADNR using the `host_group` and `server_group` statements.
**Host groups**

The host_group statement identifies the set of IP addresses to update in a name server that represents a group of hosts. ADNR updates the name server with the intersection between the IP addresses configured to ADNR in the host_group statement and the IP addresses that exist in the home lists of the hosts in the sysplex. The DNS names that are dynamically added to the name server take the form $host_group_name.domain_suffix$, where $host_group_name$ is the ADNR administrator-defined name of the group of hosts being registered to the GWM, and $domain_suffix$ is the domain suffix name specified in a zone parameter on a dns statement. To construct the DNS name, the value of the $host_group_name$ keyword of the host_group statement is used, followed by the value of the $domain_suffix$ keyword of the zone referenced in the host_group statement. The intervening dot is supplied by ADNR; do not explicitly code the dot.

ADNR can also update name servers with DNS names representing individual host instances within the sysplex, using the member keyword. ADNR updates name servers with the intersection between the IP addresses configured for the member and the set of IP addresses that exist in the home list of a particular host in the sysplex. The DNS names that are dynamically added to the name server take the form $host_name.domain_suffix$, where $host_name$ is the ADNR administrator-defined name of the member being registered to the GWM, and $domain_suffix$ is the domain suffix name specified in a zone parameter on a dns statement. To construct the DNS name, the value of the $host_name$ keyword of the host_group statement is used, followed by the value of the $domain_suffix$ keyword of the zone referenced in the host_group statement. The intervening dot is supplied by ADNR; do not explicitly code the dot. If the host_group statement contains a member keyword containing an optional $host_name$ parameter, the name server is updated with these types of DNS names.

A host_group statement can have multiple member keywords within it. One of the coded member keywords does not have to have a $host_name$ parameter. The member without a $host_name$ parameter is sometimes referred to as the unnamed member, while members with a $host_name$ parameter are sometimes referred to as named members. The IP addresses associated with the unnamed member are ones that can potentially be dynamically added to the name server with the DNS name of the form $host_group_name.domain_suffix$. Configuring an unnamed member is not required. However, a virtual unnamed member is created for you if you do not configure one.

**Result:** The IP addresses associated with the unnamed member are the union of all IP addresses explicitly configured in the unnamed member (if configured), and all IP addresses configured to all named members in that host group. In contrast, only the IP addresses explicitly configured in a named member are associated with the named member.

Typically, you configure one named member per system in the sysplex. Each named member contains IP addresses that cannot move to other systems in the sysplex.

**Guideline:** To provide reachability to the sysplex or system in case of interface failure, configure named members of host_group statements with static VIPAs. In addition, you can also code an unnamed member, and associate with it IP addresses that could potentially be moved from one system to another (DVIPAs).

Host names added to a name server using ADNR might be useful for situations when you want connectivity to the sysplex or a host in the sysplex, but the presence of a particular server is not required. For this reason, host group names would be useful for utilities such as ping or traceroute.

**Server groups**

The server_group statement identifies the set of IP addresses to update in a name server that represents a cluster of equivalent servers in the sysplex. ADNR updates the name server with the intersection between the IP addresses configured to ADNR in the server_group statement and the IP addresses on which each server in the group can be reached in the sysplex. The DNS names dynamically added to the name server take the form $server_group_name.domain_suffix$, where $server_group_name$ is the ADNR administrator-defined name of the group of servers being registered to the GWM, and $domain_suffix$ is the domain suffix name specified in a zone parameter on a dns statement. To construct the DNS name, the value of the $server_group_name$ keyword of the server_group statement is used, followed by the value of the $domain_suffix$ keyword of the zone referenced in the server_group statement. The intervening dot is supplied by ADNR; do not explicitly code the dot.
ADNR can also update name servers with DNS names representing individual server instances within the sysplex, using the member keyword. ADNR updates name servers with the intersection between the IP addresses configured for the member and the set of IP addresses on which the server can be reached on a particular host in the sysplex. The DNS names dynamically added to the name server take the form `server_name.server_group_name.domain_suffix`, where `server_name` is the ADNR administrator-defined name of the member being registered to the GWM, `server_group_name` is the ADNR administrator-defined name of the group of servers being registered to the GWM, and `domain_suffix` is the domain suffix name specified in a zone parameter on a dns statement. To construct the DNS name, the value of the `server_name` parameter of the server_group statement is used, followed by the value of the `server_name` keyword of the server_group statement, followed by the value of the `domain_suffix` keyword of the zone referenced in the host_group statement. The intervening dot is supplied by ADNR; do not explicitly code the dot. If the server_group statement contains a member keyword containing an optional `server_name` parameter, the name server is updated with these types of DNS names.

A server_group statement can have multiple member keywords within it. One of the coded member keywords does not have to have a `server_name` parameter. The member without a `server_name` parameter is sometimes referred to as the unnamed member, while members with a `server_name` parameter are sometimes referred to as named members. The IP addresses associated with the unnamed member are ones that can be dynamically added to the name server with the DNS name of the form `server_group_name.domain_suffix`. Configuring an unnamed member is not required. However, a virtual unnamed member is created for you if one is not configured.

**Result:** The IP addresses associated with the unnamed member are the union of all IP addresses explicitly configured in the unnamed member (if configured), and all IP addresses configured to all named members in that server group. In contrast, only the IP addresses explicitly configured in a named member are associated with the named member.

Typically, if affinity to a particular server instance is important, you configure one named member per server instance in the sysplex. If affinity to a particular server instance is not important, configuring only an unnamed member suffices.

**Guideline:** For high availability to the target applications to prevent reachability problems in the event of interface failure, IP addresses in server_group statements should either be static or dynamic VIPAs. If the target application is enabled to move from one TCP/IP stack to another, DVIPAs are appropriate for the server group. Otherwise, static VIPAs are appropriate.

### Uniquely identifying this ADNR instance

ADNR appears as a load balancer to the GWM that it connects to. Each load balancer must uniquely identify itself to the GWM. Therefore, each ADNR instance must be uniquely identified, to distinguish it from other ADNR instances, as well as external load balancers that connect to a GWM using SASP. Use the `uuid` (universally unique ID) statement of the ADNR configuration file to uniquely identify an ADNR instance.

According to the SASP protocol, each load balancer should be universally unique from all other load balancers. In practical terms, only load balancers that connect to the same GWM must be unique.

**Guideline:** To prevent possible future uuid conflicts among load balancer and ADNR, the uuid configured for each ADNR instance should be universally unique.

### Customizing optional statements

Customize the optional statements in the ADNR configuration file.

The optional `debug_level` statement determines how much log data is captured in the ADNR's log file.

**Restriction:** In most cases, you should not customize the `debug_level` statement, unless directed to do so by an IBM Service representative. Adding additional types of trace data can cause the amount of data captured to become voluminous. Reducing the amount of trace data from the default value might make diagnosing a problem more difficult.

Technically, the `host_group` and `server_group` statements are optional. They can be omitted to flush a name server of all ADNR-managed resource records. However, if you omit these statements, ADNR will...
not manage name servers for the sysplex until the ADNR configuration file is updated with host_group and server_group statements and the MODIFY REFRESH command is issued. When no host_group or server_group statements are configured, the ipaddrlist statement is also optional. For more information, see “Flushing a zone” on page 1184.

The key statement defines the key file used in creating digital signatures, which is used when specifying transaction signatures (TSIGs) for zone updates and zone transfers. For more information about keys, see “Authorizing dynamic updates” on page 1180 and “Authorizing zone transfers” on page 1181.

**Guideline:** Key files must have access permissions that allow ADNR to read the file, either as the file's owner or as a member of the associated group.

**Step 11: Customize the TCP/IP profiles of the TCP/IP stacks on which ADNR and the LBA applications are to run (optional)**

The TCP/IP profiles can optionally be customized to better accommodate ADNR, the Advisor, and Agents. For information about Advisor and Agent TCP/IP profile customization, see “Step 5: Customize the TCP/IP profiles of the TCP/IP stacks on which the Advisor and Agents are to run (optional)” on page 1133. You might have already performed the steps for customizing the Advisor and Agent TCP/IP profiles in “Step 6: Configure the z/OS Load Balancing Advisor function” on page 1170.

If you use dynamic VIPAs for ADNR, you need to configure the appropriate TCP/IP profiles in the sysplex for the DVIPA definition and usage. The preferred definitions include VIPARANGE with MOVEABLE NONDISRUPTIVE. For more specific information, see “Using dynamic VIPAs” on page 355.

If you are using AT-TLS, you need to perform several steps to set up the z/OS Policy Agent, enable ADNR's TCP/IP stack for AT-TLS, and so on. For more information, see “Step 5: Customize the TCP/IP profiles of the TCP/IP stacks on which the Advisor and Agents are to run (optional)” on page 1133. For ADNR, you need to customize the AT-TLS policies that are identified with the CommonTTLSConfig and TTLSConfig statements.

**Tip:** Because ADNR and the Agent are both client applications to the Advisor, you can define AT-TLS policy rules similar to the LBAdvisorAgentRule and the LBAgentRule for ADNR.

**Step 12: Start the TCP/IP stacks on which ADNR and the LBA applications are to run**

You can start ADNR before or after you start the TCP/IP stack it uses. If the TCP/IP stack that ADNR uses terminates or is not yet started, ADNR remains active and establishes communication with the TCP/IP stack when it becomes active. For additional information about the Advisor and Agents, see “Step 1: Start the TCP/IP stacks that the Advisor and the Agents will use” on page 1141.

**Step 13: Start the z/OS Load Balancing Advisor and Agent**

You can start the z/OS Load Balancing Advisor and Agents before or after ADNR. If you start ADNR before you start the Advisor, an eventual action message, EZD1272E, is displayed until the Advisor is active and a connection is successful. When a successful connection is established, ADNR issues message EZD1270I, and the Advisor issues message EZD1263I indicating that a load balancer connected. At the same time, the eventual action message is converted to a non-action message (DOMed). If Agents were not active at the time that ADNR and the Advisor established a connection, Agents report on any ADNR-registered resources that the Agent owns when the Agent becomes active. ADNR updates its name servers with that information at that time.

**Step 14: Start the target applications that are to be managed by ADNR**

ADNR can manage TCP and UDP server applications. No modifications are necessary to these applications, their configurations, or start procedures.

**Step 15: Start the ADNR application**

As ADNR connects to the Advisor, an MVS console message appears on the MVS console of the system on which ADNR is running. Simultaneously, a message appears on the Advisor’s MVS console, indicating that
a load balancer connected. If ADNR fails to connect to the Advisor, an eventual action message is displayed on ADNR’s MVS console until the connection is successful. ADNR must be started from a job control procedure that is in a procedure library. It cannot be started under BPXBATCH. The IBM-supplied program properties table has entries to make ADNR run non-swappable. You should not override this entry to make ADNR run swappable.

**Step 16: Verify that the ADNR system is functioning correctly (optional)**

View the MVS console of the ADNR system after you have started it to verify that the application started correctly and is still running. If there are any failure messages, see the appropriate message description for the appropriate corrective action. View the syslogd file of the ADNR system to see whether any error or warning messages were issued.

Use the following commands to verify that ADNR is functioning correctly:

- If connectivity cannot be established, ADNR issues the eventual action message EZD1272E, ADNR CONNECTION ATTEMPT TO GWM gwmipaddress FAILED. If this message is issued and the GWM is active, verify that routing exists between the IP addresses used by the GWM and ADNR.
- Verify that ADNR is started and connected to the expected Advisor by issuing ADNR's MODIFY procname,DISPLAY,GWM,DETAIL command. Verify that the GWM IP address and port is the expected IP address and port of the Advisor to which you intended to connect.
- From the Advisor, issue the MODIFY procname,DISPLAY,LB command to list the LB indexes known to the Advisor. Identify the LB index representing ADNR, and then issue the Advisor MODIFY procname,LB,INDEX=lb-index command. Verify that each member you have registered that you expect to be available in the sysplex displays as available in the AVAIL field. If there is a discrepancy in the availability status, check the FLAGS field for possible reasons why a member is not available. For more information about the flags in the FLAGS field for the Advisor, see z/OS Communications Server: IP System Administrator's Commands.
- Verify that server and host groups have been properly registered to the GWM by issuing ADNR's MODIFY procname,DISPLAY,GWM,GROUPS,DETAIL command. Verify that each member you have registered that you expect to be available in the sysplex displays as available in the AVAIL field. If there is a discrepancy in the availability status, check the FLAGS field for possible reasons why a member is not available. For more information about the flags in the FLAGS field for ADNR, see z/OS Communications Server: IP System Administrator's Commands.
- Verify that Agents are aware of members that they own by issuing the MODIFY procname,DISPLAY,MEMBERS Agent command. Any ADNR-registered IP addresses owned by the system where the Agent is running should appear in the display.
- Verify that ADNR is able to communicate properly with the name servers it manages by issuing ADNR's MODIFY procname,DISPLAY,DNS,ZONES, SUMMARY command. Verify that the ZONE STATUS field is or changes to SYNCHRONIZED after the convergence period expires. For the definition of the convergence period, see “Step 8: Configure ADNR to automatically restart in case of application or system failure (optional)” on page 1171. If any zone status begins with the value NOT_RESPONSIVE, there is either a connectivity problem between ADNR and the name server, or there is a configuration mismatch between ADNR and the name server. For more information about diagnosing unresponsive zones, see z/OS Communications Server: IP Diagnosis Guide. If ADNR is unable to properly communicate with a name server, ADNR issues eventual action message EZD1278E, which remains until the problem is resolved.
- Verify that name servers reflect the availability status of the sysplex resources that you have configured with ADNR. Issue ADNR's MODIFY procname,DISPLAY,ZONES,ZONEID=zone_label,DETAIL command for each zone configured to ADNR, or issue the MODIFY procname,DISPLAY,ZONES,DETAIL to view all zones. Verify that the DNS RR STATUS field for each resource record display is PRESENT for each resource that is available in the sysplex.
• Use the z/OS UNIX **dig** command to perform a zone transfer of the ADNR-managed zones, and verify that the zone contents match the expected content, based on the members configured to ADNR and the availability status of those members in the sysplex. The **dig** command to use has the following form:

```
dig @name_server_address  domain_name  axfr
```

**Tip:** If zone transfers were restricted by name server configuration to clients from specific IP addresses or from clients that have digitally signed their requests (TSIG), you might have to issue the **dig** command with the -b option or the -k option to, respectively, force the request to originate from a specific IP address or be digitally signed with the appropriate signature. For more information about the **dig** command, see z/OS Communications Server: IP System Administrator's Commands.

• Verify that ADNR is functioning correctly when using AT-TLS:
  - Use the **pasearch** command from the z/OS UNIX shell to query information from the Policy Agent. For more information about displaying policy based networking information, see z/OS Communications Server: IP System Administrator's Commands.
  - Use the Netstat TTLS/-x command to display z/OS Load Balancing Advisor and ADNR AT-TLS policies. For more information about the Netstat TTLS/-x report, see z/OS Communications Server: IP System Administrator's Commands.

---

**z/OS Load Balancing Advisor configuration considerations**

The z/OS Load Balancing Advisor solution consists of a z/OS Load Balancing Advisor application, and one or more z/OS Load Balancing Agents, per sysplex. For more information about the z/OS Load Balancing Advisor solution, see Chapter 21, “z/OS Load Balancing Advisor,” on page 1117.

**Connectivity considerations**

ADNR connects to the Advisor. The Advisor can use an access control list (ACL) to determine which load balancers are permitted to connect to it. From the Advisor's perspective, ADNR is considered to be a load balancer.

**Rules:**

- If you are not using AT-TLS, the Advisor's lb_id_list statement must include the IP address coded on the host_connection_addr keyword of the ADNR gwm statement. If you are using AT-TLS for all ADNR-Advisor connections, the lb_id_list statement and host_connection_addr keyword are ignored. If you are defining external load balancers that are not using TLS/SSL, the lb_id_list statement is required.
- The IP address and port coded on the Advisor's lb_connection_v4 or lb_connection_v6 statement must match the IP address and port coded on the gwm_id keyword of the ADNR gwm statement, depending on the address family used.

**Guideline:** For availability reasons, the IP address coded on the gwm_id keyword of the ADNR gwm statement should be a unique application-instance DVIPA.

**Near real-time availability information of sysplex resources**

To take advantage of the near real-time availability information that ADNR can provide regarding sysplex resources, clients must query the ADNR-managed name servers relatively frequently rather than use cached information from a previous name server query. The length of time that name server information is cached is typically controlled by the Time To Live (TTL) value received from the name server. A TTL is associated with each resource record in a name server, and the TTL information is part of the information that the resolver receives when the name server successfully responds to a query. ADNR provides a mechanism to define the TTL for name server resources it manages.

ADNR permits the TTL to be defined to a specific value per zone, or it can be set to a value determined by the GWM, which is the default. When the TTL value is the default value determined by the GWM, it takes on the update_interval value in the Advisor’s configuration file.
**Guideline:** Allowing the GWM to set the TTL for an ADNR zone by using the default TTL value enables clients to obtain the most accurate, near real-time sysplex resource availability information, without wasting network resources with unnecessary DNS queries.

Because ADNR can be configured to use a GWM-defined interval to set the TTL value, the GWM can dynamically change this interval. The z/OS Load Balancing Advisor does not support dynamically changing this interval, but a future Advisor implementation or other future GWM implementations might. If this occurs, ADNR has the capability to find out about the new GWM interval only when the connection to the GWM is re-established.

**z/OS Load Balancing Advisor and Agent operational considerations**

Several operational characteristics of the z/OS Load Balancing Advisor and Agent can affect ADNR.

**Advisor operational considerations**

For ADNR to accurately maintain the resource records that represent available sysplex resources in its managed name servers, the Advisor and all Agents in the sysplex need to be active. If the Advisor stops, ADNR can no longer receive information about the current availability of sysplex resources, and consequently, the resource records in the name servers that ADNR manages eventually become stale. That is, resource records are left in the name server representing sysplex resources that are no longer available, or resource records are not added to the name server to represent sysplex resources that have become available. Because of the ramifications of the Advisor becoming unavailable, you should perform the necessary configuration for optimal availability of the Advisor. For more information, see “Step 1: Configure the Advisor and Agents to automatically restart in case of application or system failure (optional)” on page 1123.

**Agent operational considerations**

If an Agent in the sysplex stops, all resource records in the ADNR-managed name servers that represent sysplex resources managed by that Agent are removed from the name server. This makes it appear as though the resources are unavailable when they actually might be available. For this reason, it is important to perform the necessary configuration for optimal availability of each Agent. For more information, see “Step 1: Configure the Advisor and Agents to automatically restart in case of application or system failure (optional)” on page 1123.

The Agent is also capable of making resources appear unavailable to ADNR by quiescing them with the Agent’s MODIFY QUIESCE command. All resource records in a name server associated with a quiesced member are removed and are not added back until the member is enabled with the Agent's MODIFY ENABLE command, or if the Agent is stopped and restarted.

**Name server configuration considerations**

The name servers that ADNR manages must support RFC 2136, *Dynamic Updates in the Domain Name System (DNS UPDATE).* For information about accessing RFCs, see Appendix G, “Related protocol specifications,” on page 1381.

Many of the subjects discussed in this topic are applicable to other name server implementations. For BIND 9 name servers, specific instructions are provided for how to accomplish configuration objectives. For other name server implementations, consult the appropriate product documentation.

**Initial zone configuration**

ADNR cannot create a zone in a name server. It can only add and delete resource records from an existing zone. The zones that ADNR manages must initially be configured to the appropriate name servers. This involves defining the zone and a small set of resource records in the zone. This includes the SOA record, the appropriate NS records, and the A or AAAA glue records.
**Rule:** Do not configure any valuable A or AAAA resource records in the zone data files that ADNR will manage. ADNR deletes any type A or AAAA resource records that were not added by ADNR, with the exception of glue resource records (see “Updates to an ADNR-managed zone” on page 1180). These resource records are deleted when ADNR starts, or during MODIFY REFRESH processing.

**Restriction:** ADNR does not support DNSSEC signed zones.

### Authorizing dynamic updates

Name servers can be configured to allow dynamic updates from only specific entities. If a name server that ADNR updates is configured to restrict which entities can update the name server, ADNR must be specifically permitted to update that name server. Name servers typically permit dynamic updates from a predetermined set of source IP addresses, sometimes referred to as an access control list (ACL), or they might require authentication with digital signatures, sometimes referred to as transaction signatures (TSIG). Authentication using digital signatures is much more secure than authenticating by source IP address, because the latter is subject to address spoofing. Furthermore, the source IP address that ADNR uses might not be entirely predictable, unless deliberate steps are taken in the TCP/IP profile to make it predictable through mechanisms like job-specific source IP address specification or other forms of SOURCEVIPA configuration. Other possible options for lessening the impact of the unpredictability of the source IP address that ADNR uses include using a subnet in the name server’s ACL. However, this allows updates from any entity in that subnet, which compromises security.

**Guideline:** Digital signatures (TSIG authentication) provide more robust authentication than source IP address permissions (ACL).

For the BIND 9 name server, dynamic updates are allowed by ACL using the allow-update statement, or by digital signatures using the update-policy or the allow-update statement.

When dynamic updates are permitted using digital signatures (TSIG), the name server and ADNR must be configured with the same shared cryptographic key. You can generate the key using the dnssec-keygen utility. Then you define the key to the name server and reference the key from name server zone definitions that want to use it.

You must also define the TSIG key to ADNR using the key configuration statement, and then reference the TSIG key from the update_key keyword of the zone keyword of the dns statement. The key file should be protected from unauthorized access. ADNR must have read access to the file. Both the .key and the .private key files generated by the dnssec-keygen utility must be present for ADNR to properly communicate with the name server, even though only the .key file name is actually specified on the update_key keyword.

### Updates to an ADNR-managed zone

Typically, zones managed by ADNR should not be updated by any entity other than ADNR. This includes manual editing of the zone data file, or dynamic updates from any other source. Many name server implementations strongly advise against manually editing the zone data file of a dynamic zone, such as the zones managed by ADNR. Editing these files has the potential to corrupt the file, or the updates can be lost. However, in general from a name server perspective, dynamic updates using a tool such as nsupdate are allowed for dynamic zones. In the case of ADNR-managed zones, certain types of dynamic updates can be made by entities other than ADNR. Table 65 on page 1180 shows which types of resource records can be dynamically added and deleted by entities other than ADNR.

<table>
<thead>
<tr>
<th>Allowed dynamic updates</th>
<th>Disallowed dynamic updates</th>
</tr>
</thead>
<tbody>
<tr>
<td>All resource record types other than A and AAAA</td>
<td>A and AAAA resource records that are not considered glue records</td>
</tr>
<tr>
<td>A and AAAA resource record types that are considered glue records</td>
<td></td>
</tr>
</tbody>
</table>
Any disallowed resource records that appear in dynamic update requests to ADNR-managed zones are accepted by the name server, but are subject to being deleted by ADNR at a later time.

**Rule:** ADNR uses a special domain name for determining whether a name server is active and configured correctly to allow dynamic updates. At times, ADNR dynamically performs an update-add and an update-delete of the following resource record:

```
ibmsasppddnsdnsprobe IN A 0.0.0.0
```

In the unlikely event that this same resource record is added to an ADNR-managed zone by an entity other than ADNR, it is subject to being deleted by ADNR in the future.

**Update forwarding**

Update forwarding is a DNS concept in some name server implementations that enables dynamic updates to be sent to a name server that is not the primary master name server for the zone being updated. The name server that receives the dynamic update request forwards the update to the primary master name server.

**Rule:** To avoid possible zone data-integrity issues, ADNR must be configured to update only the primary master name server for a zone. That is, the IP address of a name server on the dns_id keyword of the dns statement must be an address of the primary master name server for the zone identified on the domain_suffix keyword, and must not be the IP address of a secondary name server for that zone.

**Authorizing zone transfers**

Zone transfers are operations that are typically performed between authoritative name servers of a particular zone. A zone transfer occurs when all or part of the contents of a zone is sent from the name server to the requester. ADNR requests zone transfers from the primary master name server of the zones it manages. Name servers can be configured to allow zone transfers only from specific entities. If the name servers that ADNR is to update are configured to restrict which entities can perform zone transfers, ADNR must be specifically permitted to perform them. Name servers typically permit zone transfers from a predetermined set of source IP addresses, sometimes referred to as an access control list (ACL), or they can require authentication using digital signatures, sometimes referred to as transaction signatures (TSIG). Authentication using digital signatures is much more secure than authenticating by source IP address, because the latter is subject to address spoofing. Furthermore, the source IP address that ADNR uses might not be entirely predictable, unless deliberate steps are taken in the TCP/IP profile to make it predictable through mechanisms like job-specific source IP address specification or other forms of SOURCEVIPA configuration.

**Guideline:** Digital signatures (TSIG authentication) provide more robust authentication than source IP address permissions (ACL).

For the BIND 9 name server, zone transfers are allowed by ACL or by digital signatures, both by using the allow-transfer statement.

You must define the TSIG key to ADNR using the key configuration statement, and then reference the key from the transfer_key keyword of the zone keyword of the dns statement. The key file should be protected from unauthorized access. ADNR must have read access to the file. Both the .key and the .private key files generated by the dnssec-keygen utility must be present for ADNR to properly communicate with the name server, even though only the .key key file name is actually specified on the transfer_key keyword.

**Limiting the duration of an outbound zone transfer**

With some name server implementations, you can limit the amount of time that an outbound zone transfer is allowed to run. Setting this time interval to a value that is too short can have adverse affects on...
ADNR's ability to communicate with the name server. ADNR must request full zone transfers from the name servers it manages. If the period of time allowed for a zone transfer is shorter than the amount of time it normally takes to transfer an ADNR-managed zone, ADNR cannot successfully manage that zone; adjust the name server configuration to provide adequate time for a full zone transfer.

For the BIND 9 name server, the amount of time to allow for an outbound zone transfer is specified on the max-transfer-time-out option.

**Limiting the total number of simultaneous outbound zone transfers**

With some name server implementations, you can limit the total number of simultaneous zone transfer requests that are served. Setting this number too low can have adverse effects on ADNR's ability to communicate with the name server. When setting this limit, take into account the number of secondary name servers that use this name server as the master name server for their zones, as well as the number of ADNR-managed zones that are configured under this name server. During ADNR initialization and after a MODIFY REFRESH command, ADNR requests simultaneous zone transfer requests for each zone it manages. Consider the number of zones configured under the same dns statement when you are setting zone transfer limits in the name server.

For the BIND 9 name server, the total number of simultaneous outbound zone transfers allowed is specified on the transfers-out option.

**The .digrc file**

ADNR uses the z/OS UNIX dig command to perform zone transfers from managed zones. The z/OS UNIX .digrc file can provide defaults for each user for the dig command. This file is read and used if it appears in the user's home directory. Because this file can cause ADNR to function incorrectly, ADNR fails initialization if this file is found in ADNR's working directory. However, ADNR does not search for this file after initialization. ADNR's working directory is specified when ADNR is defined to the security server (RACF).

**Rule:** Do not put the .digrc file in ADNR's home directory.

**Split DNS (views)**

Split DNS is a method in some name server implementations that enables zone data to appear differently depending on which client queries the name server. For example, Internet clients might be restricted to a subset of resource records in a zone, while intranet clients might have access to all resource records in a zone.

The BIND 9 name server implementation supports split DNS through the view statement.

If you want to configure split DNS for an ADNR-managed zone, there are some special considerations. When implementing split DNS for a domain, the zone data is kept in separate files in the name server for each view of the zone. This implies that the data is disjointed, and in many respects ADNR must treat each view like a separate zone. When performing dynamic updates to a split DNS zone, the name server might determine which view to update based upon the source IP address of the nsupdate client. The BIND 9 name server uses this criteria to determine which view to update, and ADNR is the update client in this regard. Therefore, ADNR must use separate source IP addresses to update each view. This can be accomplished in the following ways:

- Configure separate ADNR applications for each view.

  By configuring an ADNR application for each view, a unique source IP address can be associated with each ADNR instance using job-specific source IP addressing. The source IP address assigned to ADNR needs to be configured appropriately in the name server. For the BIND 9 name server, the source IP address of the ADNR instance that you want to have update a specific view would appear in that view's match-clients statement.

  The easiest way for each ADNR instance to use unique source IP addresses is to run each instance on separate systems or TCP/IP stacks. If each ADNR instance must run on the same TCP/IP stack, you can use job-specific source IP addressing to provide unique source IP addresses. This involves mapping the
ADNR job names to the source IP address to be used using the JOBNAME entry in the SRCIP statement block of the TCP/IP profile. However, each ADNR instance creates multiple address spaces, whose job names are the ADNR start procedure name with a numerical digit appended (for example, the ADNR job creates the ADNR1 and ADNR2 jobs). To use this method, job-specific source IP addressing has to specify the ADNR start procedure name followed by a wildcard when specifying the job name. Also, to avoid conflicting job names of the spawned address spaces among the multiple ADNR instances, you need to name the start procedures of the ADNR jobs so that the spawned job names do not conflict. For example, the start procedure names of ADNRP and ADNRT create unique job names among their instances, such as ADNRP1 and ADNRT1; create unique source IP addresses by coding JOBNAME ADNR* source_ip_address1 and JOBNAME ADNRT* source_ip_address2.

- Understand and exploit TCP/IP's source IP address selection algorithm.

By understanding and exploiting TCP/IP's source IP address selection algorithm you can configure ADNR and locate name servers in the network, so that ADNR uses appropriate source IP addresses to dynamically update the appropriate views. For more information, see "Source IP address selection" on page 229. This technique involves coding separate dns statements in the ADNR configuration file, specifying different IP addresses for each dns statement (of the same multi-homed name server) and using the separate dns statements to update different views. If configured correctly, and depending on the IP address of the name server, the source IP address of ADNR can be influenced to match the IP address in the match-clients statement of the appropriate view in the name server.

The most predictable way to assign the correct source IP address for each separate view in this scenario is to use the DESTINATION entry in the SRCIP statement block of the TCP/IP profile. For example, if two dns statements with different IP addresses are coded in the ADNR configuration file, where each represents different views in the same name server, two DESTINATION entries are coded in the SRCIP statement of the TCP/IP profile. One DESTINATION entry contains the IP address from one of the dns statements as the destination IP address, and the second DESTINATION entry contains the IP address from the other dns statement as the destination IP address. The source IP address contained in each DESTINATION entry matches one of the IP addresses in the match-clients statement in the name server configuration file of the appropriate view to be updated.

### Zone transfer formats

Some name server implementations have the capability to send multiple resource records in a DNS message during a zone transfer operation, instead of just one resource record per DNS message. The process of sending multiple resource records per DNS message is described in RFC 2671, *Extension Mechanisms for DNS (EDNS0)*. For information about accessing RFCs, see Appendix G, “Related protocol specifications,” on page 1381.

Sending multiple resource records per DNS message is more efficient than sending just one. ADNR performs zone transfer requests from the name servers it manages. ADNR supports receiving zone transfers in either format, but is more efficient at processing the format that contains multiple resource records per DNS message.

The BIND 9 name server sends multiple resource records per DNS message by default. However, some name server implementations do not support receiving zone transfers using this format. For this reason, some name servers might be configured to use the less efficient format when sending zone data to a secondary name server. The BIND 9 name server supports specification of the zone transfer format on the transfer-format option. This option can be specified on a server statement, which can be used to set the option only when sending zone transfer information to ADNR, so that other name servers are unaffected by the setting.

### ADNR configuration considerations

This topic describes ways to change the ADNR configuration file and how to maintain zone data integrity.
Changing the ADNR configuration file

The ADNR MODIFY procname,REFRESH command provides a way to dynamically change the ADNR configuration file. Because the command does not support a file name or dataset specification, changes must be made to the same configuration file that was used when ADNR was started.

**Restriction:** Make all changes to the ADNR configuration file dynamically while ADNR is running. Changing the configuration file without using the MODIFY REFRESH command can create orphaned resource records in a name server. Orphaned resource records are resource records that are left in a name server and that ADNR has lost the ability to manage. The presence of these orphaned resource records might inaccurately direct client connections to sysplex resources that are not actually available.

**Tip:** Before making changes to the ADNR configuration file, save a backup copy of the original file under a different file name or dataset name.

You can make changes to the ADNR configuration file while ADNR is stopped, instead of using the MODIFY REFRESH command, if you take precautions to prevent orphaned resource records or you are sure that clients will no longer have their resolvers pointing to a name server with orphaned resource records. Unless you use the MODIFY REFRESH command to make changes, the following types of changes to the ADNR configuration file create orphaned resource records in name servers:

- Removing a dns statement
- Removing a zone keyword from a dns statement
- Changing the domain_suffix keyword value on a dns statement
- Changing the IP address or port of a name server on the dns_id keyword of a dns statement

**Flushing a zone**

Flushing a zone refers to deleting all ADNR-managed resource records from an ADNR-managed zone. Flushing a zone is not a normal occurrence, but might be a useful administrative tool in certain situations. You can flush all zones, or just specific zones.

Flush all zones by removing all host_group and server_group statements from the ADNR configuration file and issuing a MODIFY REFRESH command. You might flush all zones when resource records are inadvertently orphaned in a name server. The orphans can be removed by ADNR by restoring a copy of the previous configuration file, removing all host_group and server_group statements, and then issuing a MODIFY REFRESH command. When the command has completed, you can issue another MODIFY REFRESH command using the latest ADNR configuration file to return to the configuration that you want to use.

You flush individual zones in much the same way as you flush all zones. Instead of removing all host_group and server_group statements from the ADNR configuration file, you remove only those statements that reference the zone or zones that you want to flush.

**Maintaining zone data integrity**

To ensure the integrity of resource records in the name server zones that ADNR is managing, several guidelines should be followed.

**Guidelines:**

- Use the MODIFY REFRESH command to change the ADNR configuration.
- If you have modified the ADNR configuration, issue a MODIFY REFRESH command before stopping ADNR. Do not stop and restart ADNR before issuing this command.
- Do not stop ADNR until a MODIFY REFRESH command has completed.
- If message EZD1273I is issued indicating that ADNR was unable to delete a zone during a MODIFY REFRESH operation, take other steps to delete the resource records added by ADNR. This might include flushing the zone, after the underlying problem that prevented ADNR from deleting the zone is resolved. For more information, see “Flushing a zone” on page 1184.
• Do not configure multiple zones for the same domain suffix that references the same multi-homed name server.
• Do not manually edit the name server's zone data file for any zone managed by ADNR.
• Do not allow any entity other than ADNR to perform dynamic updates to the zones managed by ADNR.
• Do not employ update forwarding for ADNR-managed zones.

Steps for using the ADNR application in a sysplex subplexing environment

In a sysplex subplexing environment, there are some additional considerations for using ADNR. These steps are described in detail in the following subtopics.

Before you begin

Each subplex containing resources that were managed by ADNR before the sysplex was split into subplexes requires its own set of z/OS Load Balancing Advisor and Agent applications, and its own ADNR application, to continue to enable ADNR to manage DNS names for those subplex resources. Each subplex ADNR instance will communicate with the Advisor application in its subplex. Each subplex ADNR instance will update separate DNS zones. The ADNR instances for different subplexes cannot update the same zone, because each zone can be updated by only one ADNR application and ADNR can communicate with only one Advisor instance. There must be a one-to-one correspondence between a subplex and a DNS zone.

Procedure

Perform the following steps to use ADNR in a sysplex subplexing environment.

1. Plan how the new subdomains representing each subplex will fit into your DNS hierarchy.
2. Configure the name servers that will be updated for the new subplex domains.
3. Define and configure one Advisor per subplex.
4. Update the Agent configuration files to communicate with the Advisor running in its subplex.
5. Define one ADNR application per subplex.
6. Assign the host_group and server_group statements from the sysplex ADNR configuration to their correct subplex domains.
7. Configure the new ADNR instances to update the name server and zone for its subplex.
8. Configure the new ADNR instances to communicate with the subplex Advisor.
9. (Optional) Update resolver configuration files.
10. Start the TCP/IP stacks, Advisor, Agent, ADNR, and target applications that ADNR will manage.
11. Verify that each subplex ADNR is functioning correctly.

Step 1: Plan how the new subdomains representing each subplex will fit into your DNS hierarchy

Decide whether the new subdomain names should exist at the same level as the existing subdomain representing the sysplex that is being divided into subplexes, whether the new subdomains should become child domains of the existing sysplex domain, or whether there will be a mixture of the two.

For example, if the existing subdomain for the sysplex is mvsplex.mycorp.com, the new subdomains that represent the subplexes can be at the same level in the DNS hierarchy, such as mvsplex1.mycorp.com and mvsplex2.mycorp.com. Alternatively, you can create the new subdomains as child domains of the existing sysplex domain, such as subplex1.mvsplex.mycorp.com and subplex2.mvsplex.mycorp.com.

For the following examples, assume that the sysplex and ADNR are configured as shown in Table 66 on page 1186.
Table 66. Base sysplex and ADNR configuration

<table>
<thead>
<tr>
<th></th>
<th>Sysplex A</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Domain=mvsplex.mycorp.com</td>
</tr>
<tr>
<td>Host1</td>
<td></td>
</tr>
<tr>
<td>z/OS Load Balancing Agent</td>
<td></td>
</tr>
<tr>
<td>z/OS Load Balancing Advisor for sysplex A</td>
<td></td>
</tr>
<tr>
<td>ADNR for sysplex A updating zone mvsplex.mycorp.com</td>
<td></td>
</tr>
<tr>
<td>Host2</td>
<td></td>
</tr>
<tr>
<td>z/OS Load Balancing Agent</td>
<td></td>
</tr>
</tbody>
</table>

To convert this sysplex to a subplexing environment, one of the subplexes can use the existing domain name as the existing sysplex, and the other subplexes become subdomains of that domain, as shown in Table 67 on page 1186.

Table 67. ADNR application in a sysplex subplexing environment; Example 1

<table>
<thead>
<tr>
<th></th>
<th>Sysplex A</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>(No DNS domain)</td>
</tr>
<tr>
<td>Host1</td>
<td></td>
</tr>
<tr>
<td>Member of subplex EZBT0211</td>
<td>Domain=mvsplex.mycorp.com</td>
</tr>
<tr>
<td>z/OS Load Balancing Agent for subplex EZBT0211</td>
<td></td>
</tr>
<tr>
<td>ADNR for subplex EZBT0211 updating zone mvsplex.mycorp.com</td>
<td></td>
</tr>
<tr>
<td>Host2</td>
<td></td>
</tr>
<tr>
<td>Member of subplex EZBT0212</td>
<td>Domain=subplex0212.mvsplex.mycorp.com</td>
</tr>
<tr>
<td>z/OS Load Balancing Agent for subplex EZBT0212</td>
<td></td>
</tr>
<tr>
<td>ADNR for subplex EZBT0212 updating zone subplex0212.mvsplex.mycorp.com</td>
<td></td>
</tr>
</tbody>
</table>

Another possibility is to assign each subplex as a child domain of the original sysplex domain, as shown in Table 68 on page 1186. In this case, the existing sysplex domain no longer contains any resource records that represent hosts or server applications, but instead is merely the parent of the new subplex subdomains.

Table 68. ADNR application in a sysplex subplexing environment; Example 2

<table>
<thead>
<tr>
<th></th>
<th>Sysplex A</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>(Only delegates the child domains. Contains no sysplex resources.)</td>
</tr>
<tr>
<td>Host1</td>
<td></td>
</tr>
<tr>
<td>Member of subplex EZBT0211</td>
<td>Domain=subplex0211.mvsplex.mycorp.com</td>
</tr>
<tr>
<td>z/OS Load Balancing Agent for subplex EZBT0211</td>
<td></td>
</tr>
<tr>
<td>z/OS Load Balancing Advisor for subplex EZBT0211</td>
<td></td>
</tr>
<tr>
<td>Host2</td>
<td></td>
</tr>
<tr>
<td>Member of subplex EZBT0212</td>
<td>Domain=subplex0212.mvsplex.mycorp.com</td>
</tr>
<tr>
<td>z/OS Load Balancing Agent for subplex EZBT0212</td>
<td></td>
</tr>
<tr>
<td>z/OS Load Balancing Advisor for subplex EZBT0212</td>
<td></td>
</tr>
</tbody>
</table>
Table 68. ADNR application in a sysplex subplexing environment; Example 2 (continued)

<table>
<thead>
<tr>
<th>Host1</th>
<th>Host2</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Sysplex A</strong>&lt;br/&gt;Domain=mvsplex.mycorp.com&lt;br/&gt;(Only delegates the child domains. Contains no sysplex resources.)</td>
<td></td>
</tr>
<tr>
<td><strong>Member of subplex EZBT0211</strong>&lt;br/&gt;Domain=subplex0211.mvsplex.mycorp.com</td>
<td><strong>Member of subplex EZBT0212</strong>&lt;br/&gt;Domain=subplex0212.mvsplex.mycorp.com</td>
</tr>
<tr>
<td>ADNR for subplex EZBT0211 updating zone subplex0211.mvsplex.mycorp.com</td>
<td>ADNR for subplex EZBT0212 updating zone subplex0212.mvsplex.mycorp.com</td>
</tr>
</tbody>
</table>

Another alternative is to create new domain names for each of the subplexes at the same level of the DNS hierarchy as the existing sysplex domain, and retire the existing sysplex domain name, as shown in Table 69 on page 1187.

Table 69. ADNR application in a sysplex subplexing environment; Example 3

<table>
<thead>
<tr>
<th>Host1</th>
<th>Host2</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Sysplex A</strong>&lt;br/&gt;(No DNS domain)</td>
<td></td>
</tr>
<tr>
<td><strong>Member of subplex EZBT0211</strong>&lt;br/&gt;Domain=mvsplex0211.mycorp.com</td>
<td><strong>Member of subplex EZBT0212</strong>&lt;br/&gt;Domain=mvsplex0212.mycorp.com</td>
</tr>
<tr>
<td>z/OS Load Balancing Agent for subplex EZBT0211</td>
<td>z/OS Load Balancing Agent for subplex EZBT0212</td>
</tr>
<tr>
<td>z/OS Load Balancing Advisor for subplex EZBT0211</td>
<td>z/OS Load Balancing Advisor for subplex EZBT0212</td>
</tr>
<tr>
<td>ADNR for subplex EZBT0211 updating zone mvsplex0211.mycorp.com</td>
<td>ADNR for subplex EZBT0212 updating zone mvsplex0212.mycorp.com</td>
</tr>
</tbody>
</table>

**Step 2: Configure the name servers that will be updated for the new subplex domains**

Configure the name server or name servers with the new zones to represent the new subdomain names created for the new subplexes.

You can use the same name server that was used for the sysplex zones, or another name server or name servers. These name servers must meet the existing requirements for ADNR, as specified in “Step 3: Decide which name server or name servers are to be managed by ADNR” on page 1169. Configure any security requirements in the name server for the new zones, such as access control lists or shared keys. Delegate the new zones as child zones from their parent name servers.

If you are not planning to use the existing sysplex domain name, remove that zone from the name server configuration file on the primary and secondary name servers. Update the parent zone so that it no longer delegates to the zone that you are removing.

**Step 3: Define and configure one Advisor per subplex**

To configure one Advisor instance per subplex, see “Steps for configuring automated domain name registration” on page 1167.

Configuration includes creating the start procedure JCL, performing the required security product commands (for example, RACF), performing the actions to make the Advisor highly available in case of application or system failure, customizing the TCP/IP profiles, customizing the WLM policies for the Advisor, and so on.
Step 4: Update the Agent configuration files to communicate with the Advisor running in its subplex

Update the security mechanisms that allow the Agent to communicate with its Advisor.

You might need to update the Agent's host_connection statement to point to the Advisor running in its subplex, and the Advisor's agent_id_list statement to allow a connection from this Agent.

If you are using AT-TLS for security, see “Enabling TLS/SSL for ADNR” on page 1167 and “Enabling TLS/SSL for z/OS Load Balancing Advisor (optional)” on page 1134.

Step 5: Define one ADNR application per subplex

If resources in a subplex were previously managed by ADNR, to define one ADNR application per subplex, see the following steps (in “Steps for configuring automated domain name registration” on page 1167):

- “Step 7: Define security server profiles for ADNR” on page 1170
- “Step 8: Configure ADNR to automatically restart in case of application or system failure (optional)” on page 1171
- “Step 9: Configure and start syslogd (optional, but required to have ADNR write log messages and trace data to syslogd)” on page 1172
- “Step 10: Configure one ADNR application per sysplex” on page 1172
- “Step 11: Customize the TCP/IP profiles of the TCP/IP stacks on which ADNR and the LBA applications are to run (optional)” on page 1176

Also, for special considerations when migrating ADNR to a subplexing environment, see:

- “Step 6: Assign the host_group and server_group statements from the sysplex ADNR configuration to the correct subplex domains” on page 1188
- “Step 7: Configure the new ADNR instances to update the name server and zone for its subplex” on page 1189
- “Step 8: Configure the new ADNR instances to communicate with the subplex Advisor” on page 1189

Guideline: In a Common INET (CINET) environment, use stack affinity to ensure that each subplex ADNR instance is using a TCP/IP stack that is in the subplex. For an example of the JCL to use to establish affinity, see adnrproc.sample.

Step 6: Assign the host_group and server_group statements from the sysplex ADNR configuration to the correct subplex domains

For each host_group statement in the original ADNR configuration, identify the subplexes that contain the hosts that are in the group. Create a host_group statement in each new ADNR configuration file of the subplex that contains such a host. Configure the zone_label of each host_group statement to point to a zone statement that represents the zone that will represent the subplex. Configure the dns_label of the host_group statement to point to a dns statement that represents the name server that owns the specified zone. Create ipaddrlist statements that the host_group statements can reference, such that the IP addresses in them belong to the subplex.

For each server_group statement in the original ADNR configuration, identify the subplexes that contain the server instances that are in the group. Create a server_group statement in each new ADNR configuration file of the subplex that contains such a server instance. Configure the zone_label of each server_group statement to point to a zone statement that represents the zone that will represent the subplex. Configure the dns_label of the host_group statement to point to a dns statement that represents the name server that owns the specified zone. Create ipaddrlist statements that the server_group statements can reference, such that the IP addresses in them belong to the subplex.
Step 7: Configure the new ADNR instances to update the name server and zone for its subplex

To configure the dns statements of each subplex ADNR instance so that the correct name server and zone are updated for each subplex, see “Identifying the name servers to update and the zones to be updated in those name servers” on page 1173.

You specified the name server or name servers to be updated in “Step 2: Configure the name servers that will be updated for the new subplex domains” on page 1187. The zones that will be updated for each subplex ADNR were determined in “Step 1: Plan how the new subdomains representing each subplex will fit into your DNS hierarchy” on page 1185.

Step 8: Configure the new ADNR instances to communicate with the subplex Advisor

Configure the gwm statement of each new ADNR instance to communicate with the Advisor that represents that subplex.

Each subplex should have an Advisor that communicates with an ADNR instance, unless there are no resources in that subplex that are to be managed by ADNR. Each new ADNR instance should have a UUID on the uuid statement that is universally unique.

Step 9: Update resolver configuration files (optional)

Users who were using DNS names to connect to resources in the sysplex will be affected by converting to a sysplex subplexing environment. Some DNS names that existed before the migration will no longer exist, and users will need to use new DNS names to connect to the subplex resources.

For example, users that used the name ftp.mvsplex.mycorp.com might now need to use the domain name of the subplex that they are now required to use, such as ftp.mvsplex0212.mycorp.com. You can make some of this transition more transparent to the users by adding the new domain names to the resolver configuration files that are in use throughout your network. Consider adding the new domain names to the resolver configuration SEARCH directive.

Step 10: Start the TCP/IP stacks, Advisor, Agent, ADNR, and target applications that are to be managed by ADNR

See the following steps (in “Steps for configuring automated domain name registration” on page 1167):

• “Step 12: Start the TCP/IP stacks on which ADNR and the LBA applications are to run” on page 1176
• “Step 13: Start the z/OS Load Balancing Advisor and Agent” on page 1176
• “Step 14: Start the target applications that are to be managed by ADNR” on page 1176
• “Step 15: Start the ADNR application” on page 1176

Step 11: Verify that each subplex ADNR is functioning correctly

To verify that each subplex ADNR is functioning as expected, see “Step 16: Verify that the ADNR system is functioning correctly (optional)” on page 1177.

Operating ADNR

When ADNR is operational, you can take the following actions:

• Change the logging level of ADNR to suit your needs (optional)
• Change the ADNR configuration dynamically
• Interpret ADNR display information
Changing the logging level of ADNR

Optionally, you can change the logging level of ADNR to suit your needs. The amount of information that is logged by ADNR can be modified dynamically using the following command:

```
MODIFY procname,DEBUG,LEVEL=debug_level
```

However, modifying the logging level should be carefully considered. The IBM default value of 7 should not be changed unless instructed to do so by an IBM Service representative. For things to consider before modifying this value, see “Customizing optional statements” on page 1175.

Changing the ADNR configuration dynamically

You can change the ADNR configuration dynamically using the ADNR MODIFY procname,REFRESH command. For more information, see “Changing the ADNR configuration file” on page 1184.

Interpreting ADNR display information

For information about the MODIFY command for ADNR, including sample ADNR display information and descriptions of the output, see z/OS Communications Server: IP System Administrator’s Commands.

Diagnosing problems

ADNR must communicate with a GWM and at least one name server. Problems with this communication are obvious because there is an eventual action message on the console. Problems communicating with a name server are manifested as an eventual action message concerning the name server and separate messages for each zone under the name server, indicating that the zone is unresponsive. Configuration problems with one zone (for example, TSIG key mismatches) are manifested by an eventual action message regarding the name server and a message indicating that the particular zone is unresponsive. In all cases, successful resolution of the underlying problem results in the removal of the eventual action message. For problems communicating with the GWM and for problems communicating with a name server, see z/OS Communications Server: IP Diagnosis Guide.

Regardless of the problem communicating with a name server, ADNR sends health probes in 60-second intervals to test the reachability of the name server and determine whether ADNR and the name server have been compatibly configured. If the problem is transient (for example, a network glitch, or the name server was stopped and quickly restarted), ADNR detects when the name server is again reachable and recovers. If the problem is not transient, it is possible that the ADNR configuration, name server configuration, or both need to be changed. If only the name server configuration needs to be changed, the health probes detect when ADNR and the name server have been compatibly configured and ADNR recovers.

After starting ADNR, after restarting ADNR’s GWM, or after issuing a MODIFY REFRESH command, ADNR might be delayed for a period of time before its name servers are updated with the latest sysplex availability information. In all of these cases, after ADNR connects to a GWM, ADNR waits twice the GWM’s polling interval before attempting to update its managed name servers. This period of time is called the convergence period. For the definition of convergence period, see “Step 8: Configure ADNR to automatically restart in case of application or system failure (optional)” on page 1171. The purpose of the convergence period is to avoid making premature decisions about which sysplex resources are available or unavailable until all Agents in the sysplex have had sufficient time to receive the data registered by ADNR and report back to the Advisor, and in turn ADNR, on the availability status of those resources. After the convergence period has expired, ADNR updates its managed name servers with the latest sysplex availability information. Henceforth, ADNR updates its managed name servers immediately upon receiving updated status information from the GWM.

Upon starting ADNR or issuing a MODIFY REFRESH command, ADNR resynchronizes itself with its managed name servers. This process consists of performing an asynchronous zone transfer from the name servers of each zone managed by ADNR, and then updating the name servers using this data and the latest ADNR configuration and sysplex resource availability information. Depending on the number of sysplex resources configured to ADNR and the update_interval value configured on the Advisor, the
resynchronization and reconciliation process can take longer than the convergence period when the convergence period is short and the zones are large. When the zone status reaches SYNCHRONIZED, this process has completed and the zone should reflect the latest status information from the sysplex.

**ADNR configuration example**

This topic includes a specific configuration example of ADNR. This example assumes that the z/OS Load Balancing Advisor solution is installed.

![Figure 144. ADNR configuration example](image)

In Figure 144 on page 1191, two systems, SYSA and SYSB, are in a sysplex. The z/OS Load Balancing Advisor solution is configured and deployed in the sysplex, with the Advisor and ADNR running on SYSB and an Agent running on both SYSA and SYSB. The TN3270E Telnet server and FTPD are active on both systems. ADNR manages a name server in the network.

The following example shows an ADNR configuration file. The numbers in the left margin were added for annotation purposes and are used in the description that follows the example. This example configuration does not use subplexing or AT-TLS.

```
001 debug_level    7 # Error, Warning, Event
002 003 uuid        mycorp_sysplex_adnr
004 005 dns         network_name_server # Label used by other stmts
006       # and commands
007 008 dns_id      10.1.10.55 # Network name server
009 010 zone        mvsplex.mycorp.com_zone
011       # Label used by other stmts
012       # and commands
013 014 { domain_suffix mvsplex.mycorp.com
015 016 } # end of zone
017 018 } # end of dns
019 020 gwm         z/os_lba_advisor
021       # LBA lb_connection_v4 address
022 023 host_connection_addr 10.1.10.11 # Local address
024 } # end of gwm
025
```

}
}

} # end of server_group
In this example ADNR configuration file, the debug level is set to 7 in the optional debug_level statement on line 1. The value of 7 is the default value, so this statement is redundant but is shown for completeness. At the default level of 7, messages are written to the log if they are at error, warning, or event level. Messages at other debug levels, such as info or debug, are not written to the log file.

The uuid statement on line 3 uniquely identifies this ADNR from all other ADNR instances and external load balancers. In this example, it is a character string giving some useful information about the location of the ADNR application.

There is one name server that ADNR will manage in this example, which is represented by the dns statement on line 5. The statement is given a label of network_name_server that is used for references from other statements, like host_group and server_group, and might be used in display commands. This dns statement is referenced on lines 30, 82, and 114.

The dns_id keyword within the dns statement on line 8 tells ADNR how to reach the name server. The name server configured is at address 10.1.10.55, listening on port 53. The port is not explicitly specified because the default port is being used.

The zone keyword within the dns statement on line 10 indicates which zones ADNR manages at the name server indicated on the dns_id keyword. There can be multiple zone keywords in this statement. However, in this example, only one zone is managed by ADNR in this name server. The zone keyword has the label mvsplex.mycorp.com_zone, which is used for references from other statements like host_group and server_group. In this example, the zone is referenced on lines 31, 83, and 116.

The domain_suffix keyword within the zone keyword on line 14 assigns the domain suffix to be used for all updates to the zone. In this example, the domain suffix of mvsplex.mycorp.com is appended to the host names that ADNR creates when it adds resource records to the name server. In this example, one of the resource records added to the name server is ztelnet.mvsplex.mycorp.com. Because the zone keyword containing this domain suffix is under the dns statement representing the name server at 10.1.10.55, this implies that the name server at 10.1.10.55 is configured as the primary master name server for the mvsplex.mycorp.com domain.

The gwm statement on line 20 describes how ADNR communicates with the GWM. The gwm statement has a label of z/os_lba_advisor.
The gwm_id keyword on line 22 identifies the IP address and port on which the GWM is listening for connections from load balancers. In this example, the GWM is located at 10.1.5.1 and is listening on port 3860 for load balancer connections. The port of 3860 on the gwm_id keyword does not need to be specified because that is the default port for this keyword. However, it is explicitly coded in this example for clarity. ADNR establishes a long-lived TCP connection to the GWM.

• Line 23:
The host_connection_addr keyword of the gwm statement on line 23 identifies the source IP address that ADNR uses when connecting to the GWM. The host_connection_addr keyword is optional if you are using AT-TLS. In this example, 10.1.10.11 is used. The GWM might require configuration to enable a load balancer to connect from this address. Because the Advisor is acting as the GWM, it requires either that the source IP address of all load balancers that connect to it appear in an access control list or that AT-TLS is used. This list is defined by the lb_id_list statement in the Advisor. Therefore, in this example, 10.1.10.11 must appear in the Advisor’s lb_id_list statement to enable ADNR to connect to it.

• Line 26:
The host_group statement defines a set of IP addresses to potentially add to the ADNR-managed name server, which represents the hosts in the sysplex. They are used to map names for the hosts to IP addresses in the name server. This is one of the traditional uses of resource records in a name server. In this example, production_sysplex is the label for this host_group on line 26. This label can be used in display commands. There can be multiple host_group statements in an ADNR configuration file, although only one is shown in this example.

• Lines 29 and 31:
The host_group_name keyword identifies the DNS host name that is associated with all IP addresses identified in this host_group statement. The value of the host_group_name keyword, prodplex on line 29 in this example, is prepended to the domain suffix identified by the zone keyword of this host_group statement on line 31. In this example, all IP addresses identified by the ipaddrlist statements in this host_group statement have the potential to be added to the name server with the name prodplex.mvsplex.mycorp.com. The IP addresses that are actually added to the name server with this name are the intersection of all of the IP addresses identified in all ipaddrlist keywords in this host_group statement, with the addresses that exist in the union of all home lists in the sysplex. This assumes that an Agent is running on all systems in the sysplex. If an address is removed from the home list of a system in the sysplex (for example, using VARY TCPIP,OBEYFILE), all resource records associated with that IP address are update-deleted from the ADNR-managed name server. Similarly, if an IP address is added to the home list of a system in the sysplex and that address is already represented in this host_group statement, one or more resource records with that IP address are update-added to the ADNR-managed name server. The number of resource records added depends upon ADNR configuration. Assuming that all IP addresses configured to this host group actually exist in the sysplex, the following resource records are added to the ADNR-managed name server (TTLs are omitted):

<table>
<thead>
<tr>
<th>prodplex.mvsplex.mycorp.com</th>
<th>IN A</th>
<th>10.1.1.22</th>
</tr>
</thead>
<tbody>
<tr>
<td>prodplex.mvsplex.mycorp.com</td>
<td>IN A</td>
<td>10.1.10.22</td>
</tr>
<tr>
<td>prodplex.mvsplex.mycorp.com</td>
<td>IN A</td>
<td>10.1.1.1</td>
</tr>
<tr>
<td>prodplex.mvsplex.mycorp.com</td>
<td>IN A</td>
<td>10.1.10.1</td>
</tr>
</tbody>
</table>

Thus, the DNS name prodplex.mvsplex.mycorp.com can be used by a client to reach any system in the sysplex. Because there is no guarantee that a server is listening on each of these addresses, this DNS name should not be used by clients to connect to servers in the sysplex. This DNS name is probably most useful for utilities like ping and traceroute.

• Line 30:
The dns keyword in the host_group statement on line 30 identifies the name server that is to be updated for this host group. The dns keyword identifies this name server by the label network_name_server, which is a label on a dns statement (line 5 in this example). Thus, in this example, the names for this host_group statement are added to the name server located at 10.1.10.55.
The zone keyword of the host_group statement on line 31 identifies the zone to which the names for this host group are to be added. In this example, the label mvsplex.mycorp.com_zone matches a zone keyword label in the dns statement on line 10. Because multiple zone keywords are possible in a dns statement, the zone within the dns statement must be identified from all host_group and server_group statements. The zone keyword in the host_group statement is how the domain suffix is determined for this host_group statement.

• Lines 36 and 45:
This host_group statement contains two member definitions on lines 36 and 45. Both of these member definitions are named members because they contain a host_name keyword. An unnamed member has no host_name keyword. You can code one unnamed member per host_group. However, if one is not coded, a virtual unnamed member is created for you. A virtual unnamed member contains the union of all IP addresses coded in named members within that host group. An explicitly coded unnamed member also contains the union of all IP addresses coded in the named members that belong to that host group, in addition to any IP addresses coded in the unnamed member itself. An explicitly coded unnamed member might be useful for configuring movable dynamic VIPAs that do not always belong to a specific host.

• Line 40:
The first member definition in this host_group statement contains the host_name keyword with a value of sysa. All IP addresses that are coded in this member belong to the sysa system. The value sysa of the host_name keyword on line 40 is prepended to the domain suffix for this host group to create the name sysa.mvsplex.mycorp.com. Assuming that all IP addresses configured to this member actually exist on sysa, the following resource records are added to the ADNR-managed name server (TTLs are omitted):

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>IP Address</th>
</tr>
</thead>
<tbody>
<tr>
<td>sysa.mvsplex.mycorp.com</td>
<td>A</td>
<td>10.1.1.22</td>
</tr>
<tr>
<td>sysa.mvsplex.mycorp.com</td>
<td>A</td>
<td>10.1.10.22</td>
</tr>
</tbody>
</table>

Thus, the DNS name sysa.mvsplex.mycorp.com can be used to specifically connect to the sysa system. This name might be useful for ping or traceroute.

• Line 45:
The second member definition in the host_group statement on line 45 represents IP addresses that are to be associated with the sysb system, like the first member definition associated IP addresses with the sysa system. Assuming that all IP addresses configured to this member actually exist on sysb, the following resource records are added to the ADNR-managed name server (TTLs are omitted):

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>IP Address</th>
</tr>
</thead>
<tbody>
<tr>
<td>sysb.mvsplex.mycorp.com</td>
<td>A</td>
<td>10.1.1.1</td>
</tr>
<tr>
<td>sysb.mvsplex.mycorp.com</td>
<td>A</td>
<td>10.1.10.1</td>
</tr>
</tbody>
</table>

Similar to the first member definition, the sysb.mvsplex.mycorp.com DNS name can be used to specifically connect to the sysb system.

• Lines 41, 42, 50, and 51:
The two ipaddrlist keywords in each of the two members of the host_group statement (lines 41, 42, 50, and 51) specify the IP addresses that belong to this host group. As this example shows, multiple ipaddrlist keywords are allowed and the group represents the union of all ipaddrlist statements in the host_group statement. Each ipaddrlist statement can contain multiple IP addresses, although this example has only one IP address per ipaddrlist statement. In this host_group statement, the two ipaddrlist keywords in the first member (lines 41 and 42) reference ipaddrlist statements with the labels sysa_vipa_addrs and sysa_non_vipa_addrs at lines 56 and 61, and the two ipaddrlist keywords in the second member (lines 50 and 51) reference the ipaddrlist statements with the labels sysb_vipa_addrs and sysb_non_vipa_addrs at lines 66 and 71. Thus, the IP addresses 10.1.1.22 and 10.1.10.22 are associated with this host group, as are the IP addresses 10.1.1.1 and 10.1.10.1, as reflected in the IP addresses associated with the name prodplex.mvsplex.mycorp.com as previously shown. Furthermore, the IP addresses of the first member, 10.1.1.22 and 10.1.10.22, are associated with system sysa, as reflected in the IP addresses associated with the name sysa.mvsplex.mycorp.com, and the IP
addresses in the second member, 10.1.1.1 and 10.1.10.1, are associated with system sysb, as reflected in the IP addresses associated with the name sysb.mvsplex.mycorp.com.

• Lines 56, 61, 66, and 71:

This example shows four ipaddrlist statements, each with one IP address, at lines 56, 61, 66, and 71. There can be multiple ipaddrlist statements and each can have multiple IP addresses. Each ipaddrlist statement has a label that is referenced from host_group and server_group statements. The labels in this example are sysa_vipa_addrs, sysa_non_vipa_addrs, sysb_vipa_addrs, and sysb_non_vipa_addrs. This example shows only IPv4 addresses, but IPv6 addresses can also be coded in ipaddrlist statements. The sample ADNR configuration file shows examples of IPv6 addresses coded in ipaddrlist statements. The sample ADNR configuration file can be found in the EZBADNRC member of SEZAINST.

• Lines 58, 63, 68, and 73:

The ipaddr keyword on lines 58, 63, 68, and 73 identifies a single IP address to register. This example shows only IPv4 addresses, but IPv6 addresses can also be coded in ipaddrlist statements. The sample ADNR configuration file shows examples of IPv6 addresses coded in ipaddrlist statements. The sample ADNR configuration file can be found in the EZBADNRC member of SEZAINST.

• Lines 76 and 108:

This example shows two server_group statements; one at line 76 to represent the TN3270E Telnet servers in the sysplex, and the other at line 108 to represent the FTP daemons in the sysplex. The server_group statements are used to create DNS names in the name server that map to IP addresses, which can actually be used to reach an active instance of the server.

• Line 76:

The first server_group statement on line 76 is given the label tn3270_group. This label can be used in display commands. This group represents TN3270E Telnet servers in the sysplex.

• Line 79:

The port keyword on line 79 in the first server_group statement indicates the port that the TN3270E Telnet servers listen on, which is 23 in this example.

• Line 80:

The protocol keyword on line 80 in the first server_group statement indicates the protocol of the listening application (TCP or UDP). Because the TN3270E Telnet server is a TCP application, the value for this keyword is TCP.

• Line 81:

The server_group_name keyword on line 81 identifies the DNS host name that is associated with all IP addresses identified in this server_group statement. The value of the server_group_name keyword, ztelnet in this example, is prepended to the domain suffix identified by the zone keyword of this server_group statement. In this example, all IP addresses identified by the ipaddrlist statements in this server_group statement have the potential to be added to the name server with the name ztelnet.mvsplex.mycorp.com. The IP addresses that are actually added to the name server with this name are the intersection of all of the IP addresses identified in all ipaddrlist keywords in this server_group statement, with the addresses on which the server instances in the sysplex are available. In the case of TCP applications, this is the set of IP addresses that the servers are listening on, and for UDP applications, this is the set of IP addresses to which the servers are bound. This assumes that an Agent is running on all systems in the sysplex. The TN3270E Telnet server listens on INADDR_ANY, so in effect, it listens on all IP addresses available. If a server instance is stopped (or abnormally terminates), all resource records associated with that server instance are update-deleted from the ADNR-managed name server. Similarly, if a new server instance in that group is started and an IP address on which that server instance is available is already coded in the server_group statement, one or more resource records with that IP address are update-added to the ADNR-managed name server. The number of resource records added depends upon ADNR configuration. Assuming the TN3270E
Telnet servers are running on sysa and sysb, the following resource records are added to the ADNR-managed name server (TTLs are omitted):

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Address</th>
</tr>
</thead>
<tbody>
<tr>
<td>ztelnet.mvsplex.mycorp.com</td>
<td>A</td>
<td>10.1.1.22</td>
</tr>
<tr>
<td>ztelnet.mvsplex.mycorp.com</td>
<td>A</td>
<td>10.1.1.1</td>
</tr>
</tbody>
</table>

Thus, the DNS name ztelnet.mvsplex.mycorp.com can be used to reach any available TN3270E Telnet server in the sysplex.

- Lines 82 and 83:
  On lines 82 and 83, the dns and zone keywords of the server_group statement serve the same purpose as those keywords on the host_group statement.

- Lines 87 and 97:
  There are two named members defined in the server_group statement on lines 87 and 97. Named members contain a server_name keyword, but unnamed members do not. As in host_group statements, you can code one unnamed member per server group. However, if one is not coded, a virtual unnamed member is created for you. A virtual unnamed member contains the union of all IP addresses coded in named members within that server group. An explicitly coded unnamed member also contains the union of all IP addresses coded in the named members that belong to that server group, in addition to any IP addresses coded in the unnamed member itself. The IP addresses in the unnamed member, whether explicitly coded or not, are associated with the group name. In this example, the IP addresses of the unnamed member for this server_group statement are associated with the name ztelnet.mvsplex.mycorp.com. Coding an explicit unnamed member without any named members might suffice for servers where affinity to a particular instance is not needed. Also, if an application instance is freely movable from one system to another, or from one TCP/IP stack to another, coding an unnamed member without any named members might be acceptable. In this case, code the DVIPAs on which the application could be reached in the unnamed member. If, however, it is important for clients to be able to connect to specific instances of a server, you must code separate named members for each instance.

- Line 91:
  The first member definition in this server_group statement contains the server_name keyword with a value of telnetprimary at line 91. All IP addresses that are coded in this member are IP addresses that one instance of the TN3270E Telnet server could potentially be listening on. The value telnetprimary of the server_name keyword is prepended to the DNS name created for the server group to create the name telnetprimary.ztelnet.mvsplex.mycorp.com. Assuming that the IP address configured to this member actually exists on sysa, and that the TN3270E Telnet server is active on this system, the following resource record is added to the ADNR-managed name server (TTLs are omitted):

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Address</th>
</tr>
</thead>
<tbody>
<tr>
<td>telnetprimary.ztelnet.mvsplex.mycorp.com</td>
<td>A</td>
<td>10.1.1.22</td>
</tr>
</tbody>
</table>

Thus, the DNS name telnetprimary.ztelnet.mvsplex.mycorp.com can be used to specifically connect to the TN3270E Telnet server instance on sysa.

- Line 97:
  The second member definition in this server group on line 97 is similar to the first, with the exception that this member identifies an application instance on system sysb instead of the one on system sysa. Assuming that the IP address configured to this member actually exists on sysb, and that the TN3270E Telnet server is active on this system, the following resource record is added to the ADNR-managed name server (TTLs are omitted):

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Address</th>
</tr>
</thead>
<tbody>
<tr>
<td>telnetsecondary.ztelnet.mvsplex.mycorp.com</td>
<td>A</td>
<td>10.1.1.1</td>
</tr>
</tbody>
</table>

Thus, the DNS name telnetsecondary.ztelnet.mvsplex.mycorp.com can be used to specifically connect to the TN3270E Telnet server instance on sysb.

- Line 108:
  The second server_group statement on line 108 is similar to the server_group statement for the TN3270E Telnet servers, except that it represents FTP daemons in the sysplex. Thus, the value of the port keyword specifies the port number on which the FTP daemon listens. The server_group_name
value specifies a name that is appropriate to a group of equivalent FTP daemons. This server group has one unnamed member and no named members. Thus, the resource records that can potentially be added to the name server are as follows:

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Address</th>
</tr>
</thead>
<tbody>
<tr>
<td>zftp.mvsplex.mycorp.com</td>
<td>IN A</td>
<td>10.1.1.22</td>
</tr>
<tr>
<td>zftp.mvsplex.mycorp.com</td>
<td>IN A</td>
<td>10.1.1.1</td>
</tr>
</tbody>
</table>

### ADNR display examples

The displays in this topic use the example configuration described in “ADNR configuration example” on page 1191. The numbers in the left margin were added for annotation purposes and are used in the descriptions of the displays. Only a subset of the possible types of displays are shown in this example. For more examples of the MODIFY command for ADNR, see z/OS Communications Server: IP System Administrator’s Commands.

The following display shows information about the gwm:

```
01 F ADNR,DISP,GWM,DETAIL
02 EZD1254I GWM DETAIL
03 GWM LABEL  : Z/OS_LBA_ADVISOR
04 GWM STATUS  : CONVERGENCE_PENDING
05 GWM TIMESTAMP: 10/19/05 18:32:52
06 GWM IPADDR..PORT: 10.1.1.1..3860
07 LOCAL IPADDR  : 10.1.10.11
08 UUID         : MYCORP_SYSPLEX_ADNR
09 UPDATE INTERVAL: 60
10 LAST UPDATE  : N/A
11 1 OF 1 RECORDS DISPLAYED
```

The following comments refer to the previous display:

- Line 3:
  The GWM LABEL field on line 3 is taken from the gwm statement label on line 20 of the example ADNR configuration file. All labels and names in ADNR displays are displayed in uppercase regardless of how they appear in the ADNR configuration file.

- Line 4:
  The GWM STATUS on line 4 is CONVERGENCE_PENDING, which is a transient state meaning that the ADNR host_group and server_group information has successfully been registered with the GWM, and ADNR is waiting for a timer to expire before updating the name servers with information from this GWM.

- Line 5:
  The GWM TIMESTAMP field on line 5 shows the date and time when the most recent update of the GWM STATUS field occurred.

- Line 6:
  The GWM IPADDR..PORT field shows the IP address and port of the GWM. These values are taken from the gwm_id keyword of the gwm statement on line 22 of the example configuration file.

- Line 7:
  The LOCAL IPADDR field is the source IP address that ADNR uses when communicating with the GWM. The value of 10.1.10.11 was taken from the host_connection_addr keyword on line 23 of the example configuration file.

- Line 8:
  The UUID field value on line 8 is taken from the uuid statement on line 3 of the example configuration file.

- Line 9:
The update interval of 60 seconds is determined by GWM configuration. For the z/OS Load Balancing Advisor, this value is determined by the Advisor’s update_interval statement.

• Line 10:
The LAST UPDATE field on line 10 shows the most recent date and time that status information was received from the GWM on any of the sysplex resources that ADNR registered with the GWM. The value N/A indicates that no status updates have been received yet.

• Line 11:
The number of records displayed on line 11 indicates the number of GWMs actually displayed. Currently, this value is always 1, because only one GWM is supported.

The following display was created after the convergence timer expired. The GWM’s status changes to GWM_ACTIVE on line 4. Any status updates from the GWM will now be reflected in the name servers, provided that the name servers are reachable and configured correctly.

```
01 F ADNR,DISP,GWM,DETAIL
02 EZD1254I GWM DETAIL
03 GWM LABEL : Z/OS_LBA_ADVISOR
04 GWM STATUS : GWM_ACTIVE
05 GWM TIMESTAMP : 10/19/05 18:34:55
06 GWM IPADDR..PORT : 10.1.5.1..3860
07 LOCAL IPADDR : 10.1.10.11
08 UUID : MYCORP_SYSPLEX_ADNR
09 UPDATE INTERVAL : 60
10 LAST UPDATE : 10/19/05 18:35:29
11 1 OF 1 RECORDS DISPLAYED
```

The following display summary shows the host groups and server groups that were defined:

```
01 F ADNR,DISP,GWM,GROUPS
02 EZD1254I GWM GROUP SUMMARY
03 GWM LABEL : Z/OS_LBA_ADVISOR
04 GWM STATUS : GWM_ACTIVE
05 GROUP LABEL : PRODUCTION_SYSPLEX
06 GROUP NAME : PRODPLEX
07 GROUP LABEL : TN3270_GROUP
08 GROUP NAME : ZTELNET
09 GROUP LABEL : FTP_GROUP
10 GROUP NAME : ZFTP
11 3 OF 3 RECORDS DISPLAYED
```

The following comments refer to the previous display:

• Lines 3 and 4:
Lines 3 and 4 show the same information as the DETAIL display.

• Lines 5, 7, and 9:
The GROUP LABEL fields on lines 5, 7, and 9 show the labels of the groups that were defined to ADNR on lines 26, 76, and 108, respectively, in the example ADNR configuration file.

• Lines 6, 8, and 10:
The GROUP NAME fields on lines 6, 8, and 10 show the names from the host_group_name or server_group_name keywords on lines 29, 81, and 113, respectively, of the example ADNR configuration file.

• Line 11:
The number of records displayed on line 11 indicates the number of groups actually displayed. When the number of groups defined exceeds the MAX parameter value (or the default of 100) of the MODIFY ADNR,DISPLAY command, the difference between the numbers on this line indicates the number of groups that were omitted from the display as a result of the MAX parameter value.
The following display shows the details of one group, and demonstrates how a label can be used in a display command:

```
01 F ADNR,DISP,GWM,GROUPS,GROUPID=PRODUCTION_SYSPLEX,DETAIL
02 EZD1254I GWM GROUP DETAIL
03 GWM LABEL       : Z/OS_LBA_ADVISOR
04 GWM STATUS      : GWM_ACTIVE
05 GWM TIMESTAMP   : 10/20/05 13:15:19
06 GWM IPADDR..PORT: 10.1.5.1..3860
07 LOCAL IPADDR    : 10.1.10.11
08 UUID            : MYCORP_SYSPLEX ADNR
09 UPDATE INTERVAL : 60
10 LAST UPDATE     : 10/20/2005 13:17:21
11 GROUP LABEL     : PRODUCTION_SYSPLEX
12 GROUP NAME      : PRODPLEX
13 GROUP TYPE      : HOST
14 DNS LABEL       : NETWORK_NAME_SERVER
15 ZONE LABEL      : MVSPLEX.MYCORP.COM_ZONE
16 MEMBER HOSTNAME:
17   IPADDR        : 10.1.1.22
18   AVAIL         : YES
19   FLAGS         :
20   UPDATE COUNT  : 1
21   IPADDR        : 10.1.10.22
22   AVAIL         : YES
23   FLAGS         :
24   UPDATE COUNT  : 1
25   IPADDR        : 10.1.1.1
26   AVAIL         : YES
27   FLAGS         :
28   UPDATE COUNT  : 1
29   IPADDR        : 10.1.10.1
30   AVAIL         : YES
31   FLAGS         :
32   UPDATE COUNT  : 1
33   MEMBER HOSTNAME: SYSA
34   IPADDR        : 10.1.1.22
35   AVAIL         : YES
36   FLAGS         :
37   UPDATE COUNT  : 1
38   IPADDR        : 10.1.10.22
39   AVAIL         : YES
40   FLAGS         :
41   UPDATE COUNT  : 1
42   MEMBER HOSTNAME: SYSB
43   IPADDR        : 10.1.1.1
44   AVAIL         : YES
45   FLAGS         :
46   UPDATE COUNT  : 1
47   IPADDR        : 10.1.10.1
48   AVAIL         : YES
49   FLAGS         :
50   UPDATE COUNT  : 1
51 1 OF 1 RECORDS DISPLAYED
```

The following comments refer to the previous display:

- Lines 3–10:
  Lines 3 through 10 show information described in previous display examples.

- Line 11:
  The GROUP LABEL field on line 11 matches the value on the GROUPID keyword on the MODIFY DISPLAY command.

- Line 13:
  The GROUP TYPE field on line 13 indicates that this group was defined as a host_group versus a server_group.

- Line 14:
  The DNS LABEL field on line 14 is the label referenced by the dns keyword on line 30 of the example ADNR configuration file, which indicates which name server is to be updated with the information from this group.

- Line 15:
The ZONE LABEL field on line 15 is the label referenced by the zone keyword on line 31 of the example ADNR configuration file, which indicates which zone in the name server is to be updated with the information from this group.

- Line 16:
  The MEMBER HOSTNAME field on line 16 is blank, indicating that this is the unnamed member for this group. Because an unnamed member was not explicitly configured for this group, this member represents the virtual unnamed member that is created for you.

- Lines 17, 21, 25, and 29:
  The IPADDR values on lines 17, 21, 25, and 29 represent the IP addresses that are automatically added to the unnamed member. These four addresses represent the union of all IP addresses coded in all members of this group.

- Lines 18, 22, 26, and 30:
  The AVAIL flags on lines 18, 22, 26, and 30 all indicate that the GWM has reported these resources as available. For IPADDRs in a host group such as this, this means the Agent owning these IP addresses is active and these addresses exist in a home list in the sysplex.

- Lines 19, 23, 27, and 31:
  The FLAGS field for each of the IP addresses on lines 19, 23, 27, and 31 is empty. If the AVAIL flags were NO for any of these IP addresses, the FLAGS field would give an indication as to why. For a list of the possible flags that can appear for the MODIFY command for ADNR, and their explanations, see z/OS Communications Server: IP System Administrator’s Commands.

- Lines 20, 24, 28, and 32:
  The UPDATE COUNT fields on lines 20, 24, 28, and 32 indicate the number of times that the availability status, as sent from the GWM, has changed for these IP addresses.

- Lines 33 and 42:
  The MEMBER HOSTNAME fields on lines 33 and 42 represent the named members that were configured in the group at lines 36 and 45 of the example ADNR configuration file. Only the IP addresses explicitly coded to these members appear in the display of these members, in contrast to the unnamed member. The remainder of the fields in these named members are equivalent to the information displayed in the unnamed member.

The following display shows information about the name server that ADNR is updating:

```
01 F ADNR,DISP,DNS,DETAIL
02 EZD1254I DNS DETAIL
03 DNS LABEL : NETWORK_NAME_SERVER
04 DNS STATUS : ACTIVE
05 DNS IPADDR..PORT: 10.1.10.55..53
06 ZONES DEFINED : 1
07 ZONES ACTIVE : 0
08 1 OF 1 RECORDS DISPLAYED
```

The following comments refer to the previous display:

- Line 3:
  The DNS LABEL field value NETWORK_NAME_SERVER is taken from the dns statement on line 5 of the example configuration file. For an explanation of all of the DNS states displayed on the MODIFY command for ADNR, see z/OS Communications Server: IP System Administrator's Commands.

- Line 5:
  The DNS IPADDR..PORT field value of 10.1.10.55..53 indicates that ADNR communicates with a name server at address 10.1.10.55 on port 53. This IP address and port are taken from the dns_id keyword on line 8 of the example configuration file.

- Line 6:
  The ZONES DEFINED field on line 6 indicates that there is one zone configured under this dns statement in the ADNR configuration file.
• Line 7:
  The ZONES ACTIVE field on line 7 indicates that the zone defined under this dns statement cannot yet be updated by ADNR. In a steady state environment, the number of active zones should match the number of defined zones. If the numbers do not match, this could be an indication of a configuration problem, a network problem, or the zone could be in the middle of the resynchronization process. For more information on the resynchronization process, see “Operating ADNR” on page 1189.

• Line 8:
  The number of records displayed on line 8 indicates the number of DNSs actually displayed. When the number of DNSs defined exceeds the MAX parameter value (or the default of 100) of the MODIFY ADNR,DISPLAY command, the difference between the numbers on this line indicates the number of DNSs that were omitted from the display as a result of the MAX parameter value.

The following display shows summary information about the zones that ADNR is updating:

```
01 F ADNR,DISP,DNS,ZONES,SUMMARY
02 EZD1254I DNS ZONE SUMMARY
03 DNS LABEL : NETWORK_NAME_SERVER
04 DNS STATUS : ACTIVE
05 ZONE LABEL : MVSPLEX.MYCORP.COM_ZONE
06 ZONE STATUS : SYNCHRONIZED
07 1 OF 1 RECORDS DISPLAYED
```

The following comments refer to the previous display:

• Line 3:
  The DNS LABEL field on line 3 indicates that information for a specific name server and its zones immediately follows. The field value is taken from the label on the dns statement on line 5 of the example configuration file. For an explanation of all of the DNS states displayed on the MODIFY command for ADNR, see z/OS Communications Server: IP System Administrator’s Commands.

• Line 5:
  The ZONE LABEL field on line 5 indicates that information for the indicated zone follows. The value for this field is taken from the label on the zone keyword (line 10 of the example configuration file) of the dns statement.

• Line 6:
  The ZONE STATUS field on line 6 shows the state of the zone. The value of SYNCHRONIZED is the expected, steady-state value for a zone. For an explanation of all of the zone states displayed on the MODIFY command for ADNR, see z/OS Communications Server: IP System Administrator’s Commands.

• Line 7:
  The number of records displayed on line 7 indicates the number of zones actually displayed. When the number of zones defined exceeds the MAX parameter value (or the default of 100) of the MODIFY ADNR,DISPLAY command, the difference between the numbers on this line indicates the number of zones that were omitted from the display as a result of the MAX parameter value.

The following display shows the status of the resource records that ADNR manages in the name server:

```
001 F ADNR,DISP,DNS,ZONES,DETAIL
002 EZD1254I DNS ZONE DETAIL
003 DNS LABEL : NETWORK_NAME_SERVER
004 DNS STATUS : ACTIVE
005 DNS IPADDR . PORT: 10.1.10.55 . 53
006 ZONES DEFINED : 1
007 ZONES ACTIVE : 1
008 ZONE LABEL : MVSPLEX.MYCORP.COM_ZONE
009 ZONE STATUS : SYNCHRONIZED
010 DOMAIN SUFFIX : MVSPLEX.MYCORP.COM.
011 ZONE TIMESTAMP : 10/20/05 14:42:05
012 TSIG FLAGS : 
013 DNS RR LABEL : PRODPLEX
014 DNS RR STATUS : PRESENT
015 TTL : 60
016 CLASS : IN
017 TYPE : A
```
018 RDATA : 10.1.1.22
019 GWM LABEL : Z/OS_LBA_ADVISOR
020 GROUP LABEL : PRODUCTION_SYSPLEX
021 LAST UPDATE : 10/20/05 14:42:02
022 DNS RR LABEL : PRODPLEX
023 DNS RR STATUS : PRESENT

090 RDATA : 10.1.1.22
091 GWM LABEL : Z/OS_LBA_ADVISOR
092 GROUP LABEL : FTP_GROUP
093 LAST UPDATE : 10/20/05 14:42:02
094 DNS RR LABEL : ZFTP
095 DNS RR STATUS : PRESENT
096 TTL : 60
097 CLASS : IN
098 TYPE : A
099 RDATA : 10.1.1.1
The following comments refer to the previous display:

- Line 12:
  The TSIG FLAGS field on line 12 indicates which type of TSIG keys are being used, if any. In this example, the update_key and transfer_key keywords were not specified for the zone under this DNS. If they had been specified, an indicator or indicators would be displayed on this line showing which types of TSIG keys are being used.

- Lines 13, 49, 67, 85, 103, 121, and 130:
  The DNS RR LABEL fields indicate the portion of the DNS name of the resource record before the domain suffix is appended. Some unique examples are on lines 13, 49, 67, 85, 103, 121, and 130. Some of these labels can be compound, like TELNETPRIMARY.ZTELNET and TELNETSECONDARY.ZTELNET on lines 121 and 130. Compound labels are created for named members of server groups. The two named members were configured in a server_group statement on lines 87 and 97 of the example ADNR configuration file. The label PRODPLEX on line 13 represents the resource records for the virtual unnamed member of the host_group statement on line 26 of the example ADNR configuration file. The labels SYSA on line 49 and SYSB on line 67 represent the named members of the host group on line 36 and 45 of the example ADNR configuration file. The label ZFTP on line 85 represents the unnamed member of the server group on line 120 of the example ADNR configuration file. The label ZTELNET on line 103 represents the virtual unnamed member of the server group on line 108 of the example ADNR configuration file. The label TELNETPRIMARY.ZTELNET on line 121 represents the named member on line 87 of the example ADNR configuration file, and the label TELNETSECONDARY.ZTELNET on line 130 represents the named member on line 97 of the example ADNR configuration file.

- Line 14:
  The fields labeled DNS RR STATUS (for example, line 14) indicate whether or not the resource record is present in the name server. Resource records representing available resources in the sysplex have a
value of PRESENT, while resource records representing unavailable resources in the sysplex have a value of NOT_PRESENT.

• Line 15:
The fields labeled TTL (for example, line 15) indicate the time to live value associated with the resource record. For more information, see “Near real-time availability information of sysplex resources” on page 1178.

• Line 16:
The fields labeled CLASS (for example, line 16) indicate the resource record class. All ADNR-managed resource records have a class value of IN.

• Line 17:
The fields labeled TYPE (for example, line 17) indicate the resource record type. ADNR-managed resource records are either A for IPv4 addresses or AAAA for IPv6 addresses.

• Line 18:
The fields labeled RDATA (for example, line 18) contain the IPv4 or IPv6 address that is in the resource record.

• Line 19:
The fields labeled GWM LABEL (for example, line 19) match the label of the gwm statement on line 20 of the example ADNR configuration file.

• Line 20:
The fields labeled GROUP LABEL (for example, line 20) indicate the group definition that is responsible for the creation of the resource record. This makes it possible to correlate this resource record with the MODIFY ADNR,DISPLAY,GWM,GROUPS,GROUPID=PRODUCTION_SYSPLEX output to see the GWM data that is related to this resource record.

• Line 21:
The fields labeled LAST UPDATE (for example, line 21) indicate the most recent time that the status of the resource record has changed from PRESENT to NOT_PRESENT, or from NOT_PRESENT to PRESENT.

• Line 139:
The number of records displayed on line 139 indicates the number of zones actually displayed. When the number of zones defined exceeds the MAX parameter value (or the default of 100) of the MODIFY ADNR,DISPLAY command, the difference between the numbers on this line indicates the number of zones that were omitted from the display as a result of the MAX parameter value.
Chapter 23. Simple Network Management Protocol

This topic describes how to configure:

- Simple Network Management Protocol (SNMP) agent (osnmpd)
- z/OS UNIX snmp or osnmp command
- NetView SNMP command
- SNMP subagents
- Open Systems Adapter (OSA) support
- Trap forwarder daemon

Before you configure, read “Understanding search orders of configuration information” on page 13. It covers important information about data set naming and search sequences.

SNMP overview

SNMP is a set of protocols that describes management data and the protocols for exchanging that data between heterogeneous systems. The protocols include both the description of the management data, defined in the Management Information Base (MIB), and the operations for exchanging or changing that information. By implementing common protocols, management data can be exchanged between different platforms with relative ease.

SNMP defines an architecture that consists of:

- Network management applications
- Network management agents and subagents
- Network elements, such as hosts and gateways

The SNMP network management application can ask agents for specific information about network elements. Conversely, agents can tell the network management application when something happens to one or more network elements. The protocol used between the network management application and agents is SNMP. The transport protocol for SNMP requests is the User Datagram Protocol (UDP).

SNMP defines both the network management data and the ways in which the data is retrieved or changed by the network management application. Examples of network management data include device definitions, counts of packets received at the IP layer, TCP connection data, and so forth. The information about the network elements is stored in the Management Information Base (MIB), which is supported by the SNMP agent and its subagents. A MIB variable (or MIB object) is a specific instance of data in a collection of objects related to a common management area. The collection is called a MIB module. Each MIB object is identified by an object identifier (OID), which is a dotted-decimal value, and by a textual name. For example, the sysUpTime MIB object, which indicates how long ago the SNMP agent initialized, is defined as follows:

<table>
<thead>
<tr>
<th>Textual name</th>
<th>Object identifier (OID)</th>
</tr>
</thead>
<tbody>
<tr>
<td>sysUpTime</td>
<td>1.3.6.1.2.1.1.3</td>
</tr>
</tbody>
</table>

The z/OS Communications Server Network Management agent and subagents, also called SNMP agent and SNMP subagents, support many standard (RFC-based) MIB modules. The SNMP TCP/IP subagent also supports enterprise-specific MIB modules. For information on MIB modules supported by the z/OS Communications Server SNMP agent and subagents, see the SNMP agent capabilities statement, shipped as file /usr/lpp/tcpip/samples/mvstcpip.caps. Additionally, enterprise-specific MIBs are documented in the /usr/lpp/tcpip/samples directory. See “TCP/IP subagent” on page 1210 for more information on enterprise-specific MIB modules supported by the TCP/IP subagent. For a complete list of MIB objects supported by the SNMP agent and subagents shipped with z/OS Communications Server, see z/OS Communications Server: IP System Administrator's Commands.
Network management application

The stations that monitor network elements run network management applications. In z/OS Communications Server, the z/OS UNIX `snmp` (or `osnmp`) command provides SNMP network management from the z/OS UNIX shell. The NetView SNMP command provides network management from the NetView command line. The z/OS UNIX `snmp` and `osnmp` commands perform exactly the same function. Both commands can be used to retrieve or change data from SNMP and monitor for asynchronous events known as notifications. An unconfirmed notification is called a trap. A confirmed notification is called an inform.

For information about the syntax and use of the `snmp` and NetView SNMP commands, see z/OS Communications Server: IP System Administrator's Commands.

SNMP protocols

This topic provides an overview of the different SNMP protocols and their capabilities. For more detailed information on the security models for each of these SNMP protocols, see “Overview of SNMP security models” on page 1209.

SNMPv1

SNMPv1, standardized in 1988, is the first and most commonly used version. It became very popular and is probably the most widely deployed of the SNMP generations today. The SNMPv1 standards define support for SNMP GET, GETNEXT, and SET operations, and for asynchronous event notifications called TRAPs. However, SNMPv1 does not support some later MIB object types, such as 64-bit counters. SNMPv1 also uses community-based security, which is not very secure.

SNMPv2

The SNMPv2 protocol standards made several attempts to address the security issues associated with the SNMPv1 protocol, with the party-based security model SNMPv2p, the user-based security model SNMPv2u, and the community-based security model SNMPv2c.

Although these attempts were not successful in addressing the major security issues, SNMPv2 did provide several improvements over SNMPv1, especially in the area of data retrieval with the support of SNMP GETBULK operations, and SNMPv2 continued providing community-based security with SNMPv2c.

SNMPv3

SNMPv3 was designed in the late 1990s, and in December of 2002 become a standard. It is defined in RFCs 3410 through 3415 [see Appendix G, “Related protocol specifications,” on page 1381]. SNMPv3 uses the basic SNMP management system and operations of SNMPv1 and SNMPv2, but adds an entirely new security architecture. The SNMPv3 architecture is modularized so that portions of it can be enhanced over time without requiring that the entire architecture to be replaced. SNMPv3 defines a framework that, among other things, includes the following models:

- Message processing model (SNMPv3)
- User-based security model
- View-based access control model

The framework is structured so that multiple models can be supported concurrently and replaced over time. For example, although there is a new message format for SNMPv3, messages that are created with the SNMPv1 and SNMPv2c formats are still supported. Similarly, the user-based security model can be supported concurrently with previously used community-based security models. In addition, SNMPv3 added other key updates to the protocol, such as the following updates:

- Improved notification support
  A new notification type, INFORM, is like a TRAP that requires an acknowledgement. If the acknowledgment is not received, the INFORM is resent.
- Trap filtering
  With SNMPv3, a TRAP can also be filtered at the sender.
Dynamic configuration

The SNMP agent can be dynamically configured using MIB modules defined in RFC 3584 and RFCs 3411 through 3415.

SNMP agent

In z/OS Communications Server, the SNMP agent is a z/OS UNIX application. It supports a maximum SNMP response packet size of 65535 bytes, and supports the following SNMP protocols:

- SNMPv1
- SNMPv2c
- SNMPv3

SNMPv2c offers protocol enhancements such as the GETBULK operation. SNMPv3 provides a network management framework that allows the use of user-based security in addition to, or instead of, the community-based security supported in SNMPv1 and SNMPv2c. The view-based access control model supported in SNMPv3 allows granular access control for MIB objects with either the user-based or community-based security models. SNMPv3 also enables dynamic changes to the SNMP agent configuration.

Overview of SNMP security models

SNMP security has evolved from community-based security to a modularized architecture that provides message security and access control.

SNMPv1 and SNMPv2c

The security model used by SNMPv1 and SNMPv2c is the community-based security model. In this model, an SNMP community is made up of an SNMP agent along with SNMP manager entities. Managers typically request management data from the agents. Each SNMP community is represented using an octet string called the community name. When the manager communicates with the agents, it uses the community name as a password to get access to the management resources. Because the community name is sent in every packet in clear view, these communications are not secure.

The access control mechanism provided by SNMPv1 is very simple. A community is allowed access to read or write objects in a management information base (MIB) tree. In most implementations, a community has access to all of the objects in the MIB, and you cannot restrict the access to a particular part of the MIB tree.

SNMPv3

SNMPv3 addresses the basic lack of security inherent in the previous SNMP versions by providing message security and access control. For message security, it introduces the User-Based Security Model (USM), which provides for authentication and privacy. Additionally, access control is provided with View-Based Access Control Model (VACM). Both USM and VACM provide for secure communications when you use SNMPv3.

User-Based Security Model (USM)

This model was designed to provide message security. USM supports both authentication (data integrity, data authentication) and privacy (protection against disclosure of message payload). For authentication, the protocols supported are HMAC-MD5 and HMAC-SHA. For privacy, CBC-DES 56-bit and AES 128-bit CFB mode are the supported symmetric encryption protocols. If you use the AES protocol, the z/OS Integrated Cryptographic Service Facility (ICSF) must be active. For detailed information about configuring ICSF, see z/OS Cryptographic Services ICSF Administrator's Guide.

View-Based Access Control Model (VACM)

VACM is used to provide access control. With VACM, users are defined to groups that are allowed to access different views or parts of the management data (MIB objects), depending on defined data access privileges.
SNMP subagents

A subagent extends the set of MIB variables supported by an SNMP agent. z/OS Communications Server supports the following subagents:

- TCP/IP subagent
- OMPROUTE subagent
- TN3270E Telnet subagent
- Network SLAPM2 subagent

For a complete list of MIB objects, see z/OS Communications Server: IP System Administrator's Commands.

The OSA-Express Direct subagent is also shipped with the z/OS Communications Server product, but is supported by the System z OSA Support Group.

TCP/IP subagent

The TCP/IP subagent in z/OS Communications Server is a z/OS UNIX application that runs in its own task in the TCP/IP address space. This subagent supports many standard (RFC-based) MIB objects. In addition, it supports MIB objects in the following enterprise-specific MIB modules:

- The IBM 3172 enterprise-specific MIB.
- The IBM MVS TCP/IP enterprise-specific MIB. This MIB defines objects to extend standard MIB tables and supports retrieval and change of TCP/IP address space configuration parameters.

For a more detailed list of all the data supported by the TCP/IP subagent, see z/OS Communications Server: IP System Administrator's Commands.

Both the TCP/IP subagent and the OSA-Express Direct subagent support management data for OSA-Express features. You should use the OSA-Express Direct subagent to obtain this management data, for the following reasons:

- Because the OSA-Express Direct subagent communicates directly with the OSA-Express features, it does not require the OSA/SF and IOASNMP applications.
- The OSA-Express Direct subagent provides more OSA management data than the TCP/IP subagent.
- Because of the support provided by the OSA-Express Direct subagent, there will be no new enhancements to the OSA management data provided by the TCP/IP subagent, and support for this data will eventually be removed in a future release.

If you are using the TCP/IP subagent's OSA management data support, and decide to switch to using the OSA-Express Direct subagent instead, you no longer need to start the OSA/SF address space and the OSA IOASNMP application. For more information about this subagent, see “OSA-Express Direct subagent” on page 1211. For information on the TCP/IP subagent's dependency on OSA/SF and IOASNMP, see “Step 4: Configure the Open Systems Adapter support” on page 1231.

The TCP/IP subagent support evolves with each release. New MIB objects might be supported, and, occasionally, old ones might be removed for functions that are no longer relevant. This is particularly true for the MIB objects in the IBM MVS TCP/IP enterprise-specific MIB. This MIB's definition is shipped as file /usr/lpp/tcpip/samples/mvstcpip.mi2. For details of the changes for each release, see the REVISION sections of this MIB module file.

The TCP/IP subagent in z/OS Communications Server provides SET support, enabling remote configuration of some TCP/IP address space parameters. The TCP/IP subagent is configured and controlled by the SACONFIG statement in the PROFILE.TCPIP data set. Systems where SNMP support is not required can disable the subagent and save system resources.

OMPROUTE subagent

The OMPROUTE subagent implements the Open Shortest Path First (OSPF) MIB variable containing OSPF protocol and state information.

The OMPROUTE subagent supports selected MIB objects defined in RFC 1850.
For a detailed description of the OMPROUTE subagent, see z/OS Communications Server: IP Configuration Reference.

TN3270E Telnet subagent

The SNMP TN3270E Telnet subagent provides Telnet transaction data for monitored Telnet connections using the SNMP protocol. For more information about configuring the TN3270E Telnet subagent, see the TNSSA_CONFIG statement in z/OS Communications Server: IP Configuration Reference.

Network SLAPM2 subagent

The z/OS Communications Server Network SLAPM2 subagent (nslapm2) enables network administrators to retrieve data to determine whether the current set of Network SLAPM2 policy definitions are performing as needed or whether adjustments need to be made. The Network SLAPM2 subagent supports the Network Service Level Agreement Performance Monitor (NETWORK-SLAPM2) MIB. For more information about the Network SLAPM2 MIB, see usr/lpp/tcpip/samples/slapm2.mi2.

For a detailed description of the nslapm2 subagent, see the information on Policy Agent and policy applications in z/OS Communications Server: IP Configuration Reference.

OSA-Express Direct subagent

The OSA-Express Direct subagent supports management data for OSA-Express features. The OSA-Express Direct subagent is shipped with the z/OS Communications Server product, but is supported by the System z OSA Support Group. The MVS started procedure name of this subagent is IOBSNMP. For a complete understanding of the management data provided by the OSA-Express Direct subagent, and information on configuring the subagent, see z Systems: Open Systems Adapter-Express Customer’s Guide and Reference.

Tip: The -c parameter in the IOBSNMP MVS started procedure, specifies the SNMP community name value for connections between the OSA-Express Direct subagent and the SNMP agent, OSNMPD. If you want to avoid externalizing this value for security reasons, you can use the MVS JCL PARMDD parameter on the EXEC statement to pass all the parameters to the subagent in a data set. For example, you could set up your IOBSNMP started procedure as follows:

```
//IOBSNMP  PROC
//* Using PARMINDD for the PARMs that were on the PROC line
//*
//IOBSNMP  EXEC PGM=IOBSNMP,TIME=1440,REGION=4096K,DYNAMNBR=5,
//   PARMDD=PARMINDD
//SYSPRINT DD  SYSOUT=* 
//SYSUDUMP DD  SYSOUT=*
//PARMINDD DD  DISP=SHR,DSN=SYS1.IOBSNMP.PARMS

The SYS1.IOBSNMP.PARMS data set could contain:
   -c my_community_name -d 0 -s TCPIP
```

For more information on the PARMDD parameter, see z/OS MVS JCL Reference.

The TCP/IP subagent also supports management data for OSA-Express features, but you should use the OSA-Express Direct subagent to obtain this management data for the following reasons:

- The OSA-Express Direct subagent communicates directly with the OSA-Express features and does not require the OSA/SF and IOASNMP applications.
- The OSA-Express Direct subagent provides more OSA management data than the TCP/IP subagent.
- The TCP/IP subagent does not support management data for OSA-Express3 or later features.
- Because of the support provided by the OSA-Express Direct subagent, there will be no new enhancements to the OSA management data provided by the TCP/IP subagent, and support for this data will eventually be removed in a future release.

If you are using the TCP/IP subagent’s OSA management data support, and decide to switch to using the OSA-Express Direct subagent instead, you no longer need to start the OSA/SF address space and the OSA IOASNMP application.
Key generation commands

The `pwtokey` and `pwchange` commands are provided to enable generation and change of keys used for authentication and encryption with SNMPv3.

For more information about `pwtokey`, see z/OS Communications Server: IP Configuration Reference. For information about `pwchange`, see z/OS Communications Server: IP System Administrator’s Commands.

Distributed Protocol Interface

The DPI is an application interface used by the SNMP agent to communicate with subagents. With DPI, you can dynamically add, delete or replace management variables supported by the SNMP agent and its subagents. z/OS Communications Server provides DPI V2.0 for z/OS UNIX C socket users and DPI V1.1 for traditional C socket users. DPI V2.0 provides additional function, making it easier to write subagents and simplifying the task of developing and administering your application.

The SNMP agent also listens on a TCP ephemeral port number (>1023) that is used for subagent communication via the DPI. You cannot control this port number because of the way ephemeral ports are given out. When the SNMP agent asks for an ephemeral port, it gets the next one available. See RFC 1228 for more information.

For more information about the DPI, see z/OS Communications Server: IP Programmer’s Guide and Reference.

Trap forwarder daemon

The trap forwarder daemon enables multiple SNMP managers to receive SNMP traps from the same TCP/IP stack. The trap forwarder daemon listens for traps on a port, usually the well-known port 162, and forwards the traps to all configured managers.

For more information about the trap forwarder daemon, see z/OS Communications Server: IP Configuration Reference.

Processing an SNMP request

Figure 145 on page 1212 illustrates the flow of processing an SNMP request when the request is for data supported by the TCP/IP subagent.

The following list describes the sequence of events that occur from the time you issue an SNMP command until you receive the response:

1. The user issues a NetView SNMP command or a z/OS UNIX `snmp` command.
2. The command processor validates and encodes the request in a Protocol Data Unit (PDU), and sends it in a UDP packet to the SNMP agent. The SNMP agent can be on the same MVS image or on a different MVS image.

3. The SNMP agent validates the request and, if necessary, sends it to an SNMP subagent. Requests for agent-oriented objects are handled by the agent and all others are handled by a subagent. To determine which objects are handled by the agent and which objects are handled by a subagent, see the **Management Information Base (MIB) objects** appendix in z/OS Communications Server: IP System Administrator's Commands.

4. The agent sends the response to the originator of the request. The command processor displays the response.

**Tip:** Although not shown in Figure 145 on page 1212, other subagents that are shipped as part of z/OS Communications Server, such as the OMPROUTE subagent, the Network SLAPM2 subagent, and the TN3270E Telnet subagent, also communicate with the SNMP agent using AF_UNIX socket calls from their own address spaces.

The SNMP agent and the SNMP subagents record trace information through the z/OS UNIX syslog daemon (syslogd) using the *daemon* facility. For more information about syslogd and specifying the daemon facility in the /etc/syslog.conf configuration file, see “Logging of system messages” on page 30.

### Deciding on SNMP security needs

The SNMP agent supports SNMPv1, SNMPv2c, and SNMPv3 security.

**Community-based security**

SNMPv1 and SNMPv2c are community-based security, where a community name (or password) is passed with a request. If the community name is recognized as one that can be used by the IP address from which the request originates, the SNMP agent processes the request.

**User-based security**

SNMPv3 provides a more powerful and flexible framework for message security and access control. Message security involves providing:

- Data integrity checking, to ensure that the data was not altered in transit
- Data origin verification, to ensure that the request or response originates from the source from which it claims to have come
- Message timeliness checking and, optionally, data confidentiality, to protect against eavesdropping

Access control is the ability to control exactly what data an individual user can read or write.

The SNMPv3 architecture introduces the User-Based Security Model (USM) for message security and the View-Based Access Control Model (VACM) for access control. The architecture supports the concurrent use of different security, access control, and message processing models. For example, community-based security can be used concurrently with USM.

USM uses the concept of a user for which security parameters (levels of security, authentication and privacy protocols, and keys) are configured at both the agent and the manager. Messages sent using USM are better protected than messages sent with community-based security, where passwords are sent in the clear and displayed in traces. With USM, messages exchanged between the manager and the agent have data integrity checking and data origin authentication. Message delays and message replays (beyond what happens normally due to a connectionless transport protocol) are protected against with the use of time indicators and request IDs. Data confidentiality, or encryption, is also available.

The use of VACM involves defining collections of data (called views), groups of users of the data, and access statements that define which views a particular group of users can use for reading, writing, or receipt in a notification.
The SNMP agent can be configured to use USM and VACM by specifying SNMPD.CONF information. SNMPv3 also introduces the ability to dynamically configure the SNMP agent using SNMP SET commands against the MIB objects that represent the agent's configuration. These MIB objects are defined in RFC 3584 and RFC 3411 through 3415. This dynamic configuration support enables addition, deletion, and modification of configuration entries either locally or remotely. Remote modification of user keys can be especially useful.

**Decide on your security needs - community-based or user-based**

If you are satisfied with the security of your existing configuration, you can continue to use community-based security with no migration. If you would like to take advantage of USM or VACM, or if you have some SNMP managers that use SNMPv3, you will need to migrate your configuration. Note that USM can be used only when both the SNMP agent and the manager requesting the data support USM, as the z/OS Communications Server SNMP agent and the `snmp` command do. VACM can be used even for community-based requests, but doing so requires migration of existing community name and trap destination definitions in PW.SRC and SNMPTRAP.DEST to SNMPD.CONF.

Even if your managers continue to be community-based, there are important advantages to migrating your PW.SRC information to SNMPD.CONF format:

- Enables users to make use of the access control mechanism provided with SNMPv3 with community-based security.
- Provides the ability to dynamically configure the z/OS SNMP agent using MIBs.
- Provides a way of easing into SNMPv3 user-based security.
- Does not require any changes to the manager configuration.

The following tables list the advantages and disadvantages of using each type of security.

<table>

</table>

For more information about security, see “Creating user keys” on page 1220.

**Step 1: Configure the SNMP agent**
Configure the SNMP agent (OSNMPD) based upon your security need. The SNMP agent accepts both SNMPv1 and SNMPv2c requests for community-based security. The SNMP agent can be configured to also use the User-based Security Model and the View-based Access Control Model. You should assign the SNMP agent and all the SNMP subagents to the same WLM service class so that they all have the same dispatching priority. Timeouts can occur if the SNMP subagents are set to a lower dispatching priority than the SNMP agent.

To configure the SNMP agent, perform the following tasks:

- “Provide TCP/IP profile statements” on page 1215
- Depending upon whether you want to use USM and VACM, see one of the following topics:
  - If you are using community-based security and do not need USM or VACM, see “Provide community-based security and notification destination information” on page 1216.
  - If you want the flexibility of using USM or VACM or community-based security, see “Provide community-based and user-based security and notification destination information” on page 1219.
- “Provide MIB object configuration information” on page 1223
- See z/OS Communications Server: IP Configuration Reference for more information about OSNMPD parameters.

### Provide TCP/IP profile statements

Update the following configuration statements in *hlq.PROFILE.TCPIP*:

```
AUTOLOG
PORT
```

There are two primary TCP/IP ports used by the SNMP agent, one for receiving incoming requests and one for sending traps to managers.
The default port used by the SNMP agent to receive incoming requests is 161. If you want the agent to use port 161 for this purpose and want to ensure that no other application uses this port, you must specify the following PORT statement in your profile data set:

```
PORT
  161 UDP OSNMPD ; SNMP Agent port for SNMP requests
```

If the agent will be started from the z/OS shell, reserve the port instead for z/OS UNIX by typing OMVS instead of OSNMPD.

If you want to define a port other than 161 for SNMP requests, take the following steps:

1. Start the agent with the -p parameter.
2. Configure management applications to use the new port:
   - For the `snmp` command, make an entry in the OSNMP.CONF file with the correct port number. For details on creating this entry, see the description for `targetAgent` in the OSNMP.CONF statement in the z/OS Communications Server: IP Configuration Reference.
   - Where supported, configure other management applications to use the new port.
3. Configure subagents to use the new port:
   a. Specify the port number to use on the SACONFIG profile statement for the TCP/IP subagent.
   b. Specify the port number to use on the ROUTESA_CONFIG profile statement for the OMPROUTE subagent.
   c. Specify the port number to use on the -p parameter when starting the Network SLAPM2 subagent.
   d. Specify the port number to use on the TNSACONFIG profile statement for the TN3270E Telnet subagent.
   e. If you are using DPI subagents other than those supplied with z/OS Communications Server, set the `SNMP_PORT` environment variable to enable user-written subagents to connect to the agent.

The SNMP agent uses port 162, by default, for sending traps to the managers specified in SNMPTRAP.DEST or SNMPD.CONF file. Port 162 should be reserved for the management application primarily responsible for trap processing. If your environment requires multiple management applications at the same IP address to receive traps, consider using the Trap Forwarder Daemon. See “Step 5: Configure the trap forwarder daemon” on page 1235 for more details. If the SNMP query engine is typically used for processing traps and other applications, such as snmp, that are only occasionally used, the following port reservations are recommended.

```
PORT
  162 UDP SNMPQE ; SNMPQuery Engine
```

You must also reserve additional ports for use by the `snmp` command by specifying

```
nnnnn UDP OMVS
```

where `nnnnn` is a number in the range 0–65535 and `nnnnn` is used as the -p parameter value on the `snmp trap` command.

If you want the SNMPQE and OSNMPD address spaces to be started automatically when the TCPIP address space is started, then include SNMPQE and OSNMPD in the AUTOLOG statement:

```
AUTOLOG
  SNMPQE ; SNMP Query Engine
  OSNMPD ; SNMP Agent
ENDAUTOLOG
```

### Provide community-based security and notification destination information

If you are using only community-based security without the view-based access control model, see the following subtopics to configure the security and trap destinations.
Provide community name information

SNMP agents are accessed by remote network management stations and by SNMP subagents. To allow network management stations to send inquiries to the SNMP agent, and SNMP subagents to connect to the SNMP agent, you can provide PW.SRC information that defines a list of community names and IP addresses that can use these community names. The community name operates as a password when accessing objects on, or connecting to, a destination SNMP agent. The subagents pass the community name to the agent on the connect request.

Guideline: Because the community name of public is a well-known name, it should not be configured to the agent due to security considerations. IBM Health Checker for z/OS can be used to check whether the community name of public has been configured to the SNMP agent. For more details about IBM Health Checker, see IBM Health Checker for z/OS: User’s Guide.

All of the z/OS Communications Server SNMP subagents connect to the agent using the IPv4 primary interface IP address of the stack with which the subagent is associated, and a community name. As long as SOURCEVIPA is not in effect on the IPCONFIG profile statement, this IP address is the source IP address that the agent uses, along with the community name, to verify the subagent’s authority to connect to the SNMP agent. The IPv4 primary interface IP address is either the first IP address in the HOME list or the IP address specified on a PRIMARYINTERFACE TCP/IP profile statement. If SOURCEVIPA is in effect, the IP address used by the agent to verify the subagent’s authority is the virtual IP address associated with the IPv4 primary interface IP address. For information on determining which virtual IPv4 address is associated with a physical IPv4 address, see the HOME statement in z/OS Communications Server: IP Configuration Reference. Check the Netstat HOME/-h output to verify the IPv4 primary interface address of the stack.

The PW.SRC information is optional. If no PW.SRC information is found and no community name is specified for the -c parameter at agent invocation, then the SNMP agent will accept requests with a community name of 'public' from any IP address. If a PW.SRC file exists, but is empty, and if no community name is specified on the -c parameter at the agent invocation, then no requests will be accepted by the agent.

Note: Verify that there is no SNMPD.CONF file because this file can be used only with SNMPv3. If an SNMPD.CONF file is found, the PW.SRC file will not be used.

If creating a data set, you can specify a sequential data set with the following attributes: RECFM=FB, LRECL=80, and BLKSZ=3120. Other data set attributes might also work, depending on your installation parameters.

**PW.SRC example**

The PW.SRC statements could be specified as follows:

| Passwd1  | 9.0.0.0 | 255.0.0.0 |
| Passwd2  | 129.34.81.22 | 255.255.255.255 |
| IPv6passwd3 | 12ab::0 | 16 |
| IPv6passwd4 | 39B3::F430:03EE | 128 |

The PW.SRC statements specify community names and hosts that can use each community name. The format of a statement is:

```
community_name desired_network snmp_mask
```

See z/OS Communications Server: IP Configuration Reference for more information about syntax.

The community name of an incoming SNMP request is compared to the known community names. If a match is found, then the IP address of the incoming request is logically ANDed with the snmp_mask of the PW.SRC statement. The result of the logical ANDing process is compared with the desired_network. If they match, the request is accepted.

In the case of a password definition to be used by an IPv6 address or range of IPv6 addresses, the snmp_mask can be specified as a prefix value. The prefix specifies the number of bits to be used to construct an IPv6 address mask.
In the preceding example, if a request for community_name passwd1 is received from the IP address 9.34.22.122, IP address 9.34.22.122 is ANDed with 255.0.0.0. The result is 9.0.0.0, which equals the specified desired_network for passwd1, so this request is accepted. In passwd2, if the community_names match, only requests from host 129.34.81.22 are accepted. The password IPv6passwd3 can be used by any IPv6 address that starts with 12ab.

If the community_name values do not match, or the IP address ANDed with the snmp_mask does not match, an AUTHENTICATION_FAILURE trap is sent if both of the following conditions are true:

- A destination entry exists in SNMPTRAP.DEST.
- Authentication failure traps have been enabled. These traps are enabled by either setting MIB object snmpEnableAuthenTraps.0 to 1, or specifying the following statement in the OSNMPD.DATA configuration information:

```
snmpEnableAuthenTraps 1
```

A desired_network and snmp_mask of all zeros allows anyone with the correct community_name to make requests. However, the passwords for IPv4 addresses and the passwords for IPv6 addresses are stored and handled separately. Defining a password for use by both IPv4 and IPv6 addresses requires two entries in PW.SRC. Likewise, defining a password to be used by all addresses (both IPv4 and IPv6) requires two entries as follows:

```
passwd5 0.0.0.0 0.0.0.0
passwd5 0::0 0
```

**Note:** By default, the SNMP agent and the snmp command send packets such that a VIPA address will be used as the originating address in the packet, if SOURCEVIPA is configured. This is a change introduced in V2R10; previously, the SNMP agent and the snmp command set a socket option to cause the physical interface addresses to be used as the originating addresses on packets they sent. That meant the PW.SRC file had to contain all of the possible physical interface addresses that might be used, rather than a smaller number of VIPA addresses. A customer can override this change in behavior, if wanted. This can be done for the SNMP agent by invoking it with the -a option. Similarly, you can do the same for the UNIX snmp command by either invoking it from the command line with the -a option, or by coding NOSVIPA in the command's OSNMP.CONF configuration file.

**Provide trap destination information**

Traps are unsolicited messages that are sent by an SNMP agent to an SNMP network management station. An SNMP trap contains information about a significant network event. The management application running at the management station interprets the trap information sent by the SNMP agent.

**Note:** When the SNMP agent starts, it retrieves an IP address for itself. If it retrieves an IPv6 colon-hexadecimal address, when it sends traps the source IP address in each trap will be 0.0.0.0.

For a detailed description of the SNMP trap types provided by z/OS CS, see z/OS Communications Server: IP System Administrator's Commands.

The SNMP agent Distributed Protocol Interface allows subagents other than those shipped with z/OS Communications Server (which might be running on another host) to generate SNMP traps. This can allow for support of other types of traps. For more information about SNMP DPI, see the z/OS Communications Server: IP Programmer's Guide and Reference.

To use traps, you must provide SNMPTRAP.DEST information defining a list of managers to which traps are sent. The SNMPTRAP.DEST information is optional. If no trap destination file is found, then the SNMP agent sends traps to the IP address of the SNMP agent and issues a warning message indicating that defaults are in effect. If a trap destination file exists, but is empty, no traps are sent.

**Guideline:** If you use SNMPTRAP.DEST to configure trap information, the agent uses the hardcoded community name of public in the outbound traps. Because the community name of public is a well-known name, it should not be used in SNMP traps due to security considerations. To configure specific community names for trap destinations, you must convert your SNMPTRAP.DEST information to a SNMPD.CONF configuration file format. For more information about how to accomplish this conversion,
see Migrating the PW.SRC file and SNMPTRAP.DEST file to the SNMPD.CONF file in z/OS Communications Server: IP Configuration Reference.

**Note:** Verify that there is no SNMPD.CONF file. If an SNMPD.CONF file is found, the SNMPTRAP.DEST file will not be used.

If creating a data set, you can specify a sequential data set with the following attributes: RECFM=FB, LRECL=80, and BLKSZ=3120. Other data set attributes might also work, depending on your installation parameters.

**SNMPTRAP.DEST example**

The SNMPTRAP.DEST statements could be specified as follows:

```
# SNMP Trap Destination information
124.34.216.1 UDP
39B3::F430:03EE UDP
MVSSYS2 UDP
```

See z/OS Communications Server: IP Configuration Reference for more information about syntax.

**Provide community-based and user-based security and notification destination information**

If you want to use user-based security, either concurrently with or instead of community-based security, you must configure security definitions and notification destinations. To allow SNMP subagents to connect to the SNMP agent using user-based security, you must configure community-based security definitions. The SNMP subagents pass the community name to the agent on the connect request. The community name operates as a password when the SNMP subagents connect to the SNMP agent.

**Guideline:** Because the community name of public is a well-known name, it should not be configured to the agent due to security considerations. IBM Health Checker for z/OS can be used to check whether the community name of public has been configured to the SNMP agent. For more details about IBM Health Checker, see IBM Health Checker for z/OS: User's Guide.

All of the z/OS Communications Server SNMP subagents connect to the agent using the IPv4 primary interface IP address of the stack with which the subagent is associated, and a community name. As long as SOURCEVIPA is not in effect on the IPCONFIG profile statement, this IP address is the source IP address that the agent uses, along with the community name, to verify the subagent's authority to connect to the SNMP agent. The IPv4 primary interface IP address is either the first IP address in the HOME list or the IP address specified on a PRIMARYINTERFACE TCP/IP profile statement. If SOURCEVIPA is in effect, the IP address used by the agent to verify the subagent's authority is the virtual IP address associated with the IPv4 primary interface IP address. For information on determining which virtual IPv4 address is associated with a physical IPv4 address, see the HOME statement in z/OS Communications Server: IP Configuration Reference. Check the Netstat HOME/-h output to verify the IPv4 primary interface address of the stack.

SNMPv3 provides the ability to configure the agent dynamically, from either a local or remote host, and to make changes in the configuration while the SNMP agent is running. Doing SNMP agent configuration dynamically requires a good understanding of how the SNMP SET commands can be issued to create new rows or to change or delete existing rows, as well as familiarity with the SNMP engine configuration tables defined in RFCs 3584 and 3411 through 3415. For information about accessing RFCs, see Appendix G, "Related protocol specifications," on page 1381.

As an alternative to dynamically configuring the SNMP agent, z/OS Communications Server supports a configuration file to be read at agent initialization called the SNMPD.CONF file. Dynamic configuration changes made with SNMP SET commands to the SNMP agent configuration entries will be written out to the SNMPD.CONF file, so they will continue to be in effect even after the SNMP agent is restarted.

**SNMPD.CONF file**

The SNMPD.CONF file defines the SNMP agent security and notification destinations. If the SNMPD.CONF file exists, the agent can support SNMPv1, SNMPv2c, and SNMPv3 requests. If no SNMPD.CONF file
exists, the agent will support only SNMPv1 and SNMPv2c requests. See Coding the SNMPD.CONF entries in z/OS Communications Server: IP Configuration Reference for descriptions of the SNMPD.CONF configuration statements.

**Note:** If the SNMPD.CONF file is found, the PW.SRC file and the SNMPTRAP.DEST files are not used.

**SNMPD.CONF dynamic configuration**

If the SNMPD.CONF information is located in an MVS data set rather than a z/OS UNIX file, special considerations must be made to support dynamic configuration changes to the SNMP agent's configuration. If dynamic configuration changes are made, the file is rewritten to reflect the changes. Therefore, consider the following items when allocating the SNMPD.CONF file to an MVS data set:

- The record length (LRECL) should be 512 bytes to accommodate the longest possible entry.
- The use of a member of a partitioned data set is tolerated but not recommended. Because the file might be rewritten often, frequent compression of the partitioned data set may become necessary. In addition, locking on the file is done at the data set level, not at the member level, so other members of the partitioned data set would not be usable while the SNMP agent was running (after a dynamic configuration change had been made).

**SNMPD.CONF example**

A sample SNMPD.CONF file is shipped as /usr/lpp/tcpip/samples/snmpd.conf. See z/OS Communications Server: IP Configuration Reference for more information about syntax.

The sample OSNMP.CONF file used by the snmp command contains entries that match the sample SNMPD.CONF data set. See “Configure the z/OS UNIX snmp command” on page 1225 for additional information on configuring the snmp command.

**Note:** By default, the SNMP agent and the snmp command send packets such that a VIPA address will be used as the originating address in the packet, if SOURCEVIPA is configured. This is a change introduced in V2R10; previously, the SNMP agent and the snmp command set a socket option to cause the physical interface addresses to be used as the originating addresses on packets they sent. That meant the SNMPD.CONF file had to contain all of the possible physical interface addresses that might be used, rather than a smaller number of VIPA addresses. A customer can override this change in behavior, if wanted, by invoking the SNMP agent with the -a option or by using either the -a option or the NOSVIPA option in the snmp command's OSNMP.CONF configuration file.

**SNMPD.BOOTS**

The SNMP agent uses the SNMPD.BOOTS configuration file to support SNMPv3 security. This file contains agent information used to authenticate the SNMPv3 requests. The SNMPD.BOOTS keeps the agent identifier and the number of times the agent reboots. If no SNMPD.BOOTS file exists when the agent is started, the agent creates one. You may want to add comments to the beginning of this file. If a file does exist, the agent uses the values specified in the file for setting its engineID and engineBoots values. If the file exists but contains incorrect values for engineID or engineBoots, the agent issues a message and terminates.

**Notes:**

1. The recommended approach is to allow the SNMP agent to create the file.
2. If the SNMPD.BOOTS file is not provided, the SNMP agent creates the file. If multiple SNMPv3 agents are running on the same MVS image, use the environment variable to specify different SNMPD.BOOTS files for the different agents. For security reasons, ensure unique engineIDs are used for different SNMP agents.

**Creating user keys**

- Authentication
  
  Authentication is generally required for SNMPv3 requests to be processed (unless the security level requested is 'noAuth'). When authenticating a request, the SNMP agent verifies that the authentication
key sent in an SNMPv3 request can be used to create a message digest that matches the message digest created from the authentication key defined for the user.

The `snmp` command uses the authentication key found on an entry in the OSNMP.CONF configuration file. It needs to correlate with the authentication key specified on a USM_USER entry for that user in the agent's SNMPD.CONF configuration file.

As an alternative to storing authentication keys in the client configuration file, the `snmp` command allows user passwords to be stored. If the `snmp` command is configured with a password, the code generates an authentication key (and privacy key if requested) for the user. These keys must, of course, produce the same authentication values as the keys configured for the USM_USER in the agent's SNMPD.CONF file or configured dynamically with SNMP SET commands. However, the use of passwords in the client configuration file is considered less secure than the use of keys in the configuration file.

The authentication key is generated from two pieces of information:

- The specified password.
- The identification of the SNMP agent at which the key will be used. If the agent is an IBM agent and its engineID was generated using the vendor-specific engineID formula, the agent may be identified by IP address or host name. Otherwise, the engineID must be provided as the agent identification.

A key that incorporates the identification of the agent at which it will be used is called a localized key. It can be used only at that agent. A key that does not incorporate the engineID of the agent at which it will be used is called nonlocalized.

Keys stored in the `snmp` command's configuration file, OSNMP.CONF, are expected to be nonlocalized keys. Keys stored in the SNMP agent's configuration file, SNMPD.CONF, can be either localized or nonlocalized, though the use of localized keys is considered more secure.

• Encryption

Keys used for encryption are generated using the same algorithms as those used for authentication. However, key lengths might differ. For example, an HMAC-SHA authentication key is 20 bytes long, but a localized encryption key used with HMAC-SHA is only 16 bytes long. The SNMP agent, z/OS UNIX `snmp` command, and the SNMP manager API use the first 16 bytes of the HMAC-SHA authentication key as the localized encryption key (also called the privacy key).

z/OS Communications Server provides a facility called `pwtokkey` that enables conversion of passwords into localized and nonlocalized authentication and privacy keys. The pwtokkey procedure takes as input a password and an identifier of the agent and generates authentication and privacy keys. Because the procedure used by the pwtokkey facility is the same algorithm used by the `snmp` command, the person configuring the SNMP agent can generate appropriate authentication and privacy keys to put in the SNMPD.CONF file for a user, given a particular password and the IP address at which the agent will run.

Use the `pwtokkey` command to convert passwords into authentication and privacy keys. See z/OS Communications Server: IP System Administrator's Commands.

Migrating community-based configuration to SNMPD.CONF format

If you want to continue to use community-based security but take advantage of some of the new SNMPv3 functions, or if you want to use the new SNMPv3 user-based security along with community-based security, you need to migrate your current configuration, defined in PW.SRC and SNMPTRAP.DEST, to SNMPD.CONF format. For information about the necessary steps for migrating PW.SRC and SNMPTRAP.DEST to SNMPD.CONF, see z/OS Communications Server: IP Configuration Reference.

Provide secure access to agent from subagents

An SNMP subagent can connect to the z/OS Communications Server SNMP agent by using the DPI API (the DPI API is documented in z/OS Communications Server: IP Programmer’s Guide and Reference) and specifying either a z/OS UNIX or a TCP connection. You can control access to the agent from subagents for both types of connections.
Connecting to the agent through z/OS UNIX

For subagents that specify a z/OS UNIX connection to the agent, a z/OS UNIX path name is used for the connection. You can configure this path name by either specifying it on the -s agent initialization parameter or specifying it as the value of the dpiPathNameForUnixStream MIB object in OSNMPD.DATA. The default path name is /var/dpi_socket.

The SNMP agent creates this path name every time it initializes. For subagents to successfully connect to the agent using this path name, either the subagents must be defined with superuser authority or the read and write file access permission bits for the path name must be set as follows:

- If the user ID of a subagent is associated with the same security product group as the agent, read and write access must be set in the Group section of the file access permission bits.
- If the user ID of a subagent is not associated with the same security product group as the agent, read and write access must be set in the Other section of the file access permission bits.

You can configure the read and write access by specifying the -C agent initialization parameter.

For more detailed information about file access permission bits and handling security for your files, see z/OS UNIX System Services User's Guide. If you need to change the file access permission bits for the path name after the agent has initialized, you can use the z/OS UNIX chmod command. For more information about the chmod command, see z/OS UNIX System Services Command Reference.

Connecting to the agent through TCP

For subagents specifying a TCP connection, you can use the installation's SAF-compliant security product [such as the z/OS Security Server (RACF)] to control which of the SNMP subagents are permitted to connect to the SNMP agent. One security product resource name can be created per TCP/IP stack per MVS image. The security product resource name is specified in the following format:

EJB.SNMPAGENT.sysname.tcpprocname

where sysname is the name of the MVS system image and tcpprocname is the TCP/IP started procedure name.

The profile must be created under the SERVAUTH class. After creating the profiles, use the security product to define the user IDs of those subagents which should be permitted to connect via TCP to the SNMP Agent. Authorization failures are documented by security product failure messages and SNMP agent traces.

Note: If you use this authorization function, only SNMP subagents which are associated with the same TCP/IP stack as the SNMP agent will be permitted to connect to the agent. Local SNMP subagents that are associated with other TCP/IP stacks, or remote SNMP subagents, will not be permitted to connect. The following ICH0408I RACF error message is issued:

ICH0408I JOB(OSNMPD) STEP(OSNMPD) EZB.SNMPAGENT.sysname.tcpprocname CL(SERVAUTH) INSUFFICIENT ACCESS AUTHORITY FROM EZB.SNMPAGENT.** (G) ACCESS INTENT(READ ) ACCESS ALLOWED(NONE )

In the ICH0408I message, only the JOB and STEP names are displayed instead of a user ID. Because the subagent was not associated with the same TCP/IP stack as the SNMP agent, the agent could not obtain the user ID.

Also, any subagents which connected to the SNMP agent before the agent security product resource name was created will not have been authorized via the security product.

You can use the control statements in the sample JCL job provided in SEZAINST(EZARACF) to define this authorization. For example, if you wanted to permit any SNMP subagents associated with a user ID of USER2 to connect to the SNMP agent you could use the following definitions:

RDEFINE SERVAUTH EZB.SNMPAGENT.MVSA.TCP1 UACC(NONE) PERMIT EZB.SNMPAGENT.MVSA.TCP1 ACCESS(READ) CLASS(SERVAUTH) ID(USER2)
Allowing subagents with duplicate identifiers to connect

When an SNMP subagent connects to the SNMP agent, an SNMP object identifier (OID) value is used as the subagent identifier. For subagents connecting using the DPI V2.0 API, the subagent supplies its OID during the connection process. All the Communications Server subagents use the DPI V2.0 API when connecting to the agent.

For subagents connecting using the DPI V1.1 API, the agent assigns a constant OID value to the subagent. Therefore, if more than one DPI V1.1 subagent connects to the agent, all the DPI V1.1 subagents are identified with the same OID value.

The SUBAGENT-MIB, supported by the SNMP agent, defines the MIB object, saAllowDuplicateIDs, that can be used to configure whether the agent should allow subagents with duplicate OID values to connect.

By default, the SNMP agent sets the value of this object to 1, which allows subagents with duplicate OID values to connect. You can configure the value of this MIB object using the OSNMPD.DATA configuration file. For more information about this file, see “Provide MIB object configuration information” on page 1223. If you do not want the agent to allow subagents with duplicate OID values to connect, set the value of this MIB object to 2.

Provide MIB object configuration information

An installation can set values for selected MIB objects by providing OSNMPD.DATA information. A sample of OSNMP.DTA is installed as file /usr/lpp/tcpip/samples/osnmpd.data. See z/OS Communications Server: IP Configuration Reference for syntax information. If no OSNMPD.DATA file is found, the defaults for these MIB objects are as follows:

Object

Default

dpiPathNameForUnixStream

The default is /var/dpi_socket. This is the z/OS UNIX path name that is used in accepting requests from subagents that communicate with the agent over z/OS UNIX connections.

The SNMP agent creates this path name every time it initializes. For subagents to successfully connect to the agent using this path name, either the subagents must be defined with superuser authority or the read and write file access permission bits for the path name must be set as follows:

- If the user ID of a subagent is associated with the same security product group as the agent, read and write access must be set in the Group section of the file access permission bits.
- If the user ID of a subagent is not associated with the same security product group as the agent, read and write access must be set in the Other section of the file access permission bits.

You can configure the read and write access by specifying the -C agent initialization parameter.

For more detailed information about file access permission bits and handling security for your files, see z/OS UNIX System Services User's Guide. If you need to change the file access permission bits for this path name after the agent has initialized, you can use the z/OS UNIX chmod command. For more information about the chmod command, see z/OS UNIX System Services Command Reference.

sysDescr

If the environment variable HOSTNAME exists, its value is used. Otherwise, the default value identifies the z/OS system under which the agent is running. The maximum length of this object is 255 octets.

sysContact

"SNMPBASE-Unspecified". The maximum length of this object is 255 octets.

sysLocation

"SNMPBASE-Unspecified". The maximum length of this object is 255 octets.

sysName

"SNMPBASE-Unspecified". The maximum length of this object is 255 octets.

sysObjectId

1.3.6.1.4.1.2.3.13
Note: sysObjectID is defined as the vendor’s authoritative identification of the network management subsystem contained in the entity. That is, it is intended to uniquely identify the SNMP agent. Changing this value is not recommended and will be disabled in a subsequent release.

sysServices
A single octet with a default of 0. See the RFC 1907 description for this object.

snmpEnableAuthenTraps
Default value is 2, which means traps are disabled.

saDefaultTimeout
5 seconds.

saMaxTimeOut
600 seconds.

saAllowDuplicateIDs
Default is 1, which means multiple instances of a subagent (that is, where the subagent identifier for all the subagents is the same) are allowed to connect to the SNMP agent. To prevent multiple instances of a subagent from connecting to the SNMP agent, set the value to 2.

Note: Because a subagent identifier cannot be specified for subagents connecting using the DPI V1.1 API, the SNMP agent assigns the same constant identifier for all DPI V1.1 subagents. Therefore, this object must be set to 1 to allow multiple DPI V1.1 subagents to run concurrently. For more information about subagent identifiers, see “Allowing subagents with duplicate identifiers to connect” on page 1223.

For information about where these MIB objects are defined, see z/OS Communications Server: IP User’s Guide and Commands.

If creating a data set, you can specify a sequential data set with the following attributes: RECFM=FB, LRECL=80, and BLKSZ=3120. Other data set attributes might also work, depending on your installation parameters.

Common INET considerations
If you have configured a common INET (CINET) environment where multiple TCP/IP stacks are active, and you want to run multiple SNMP agents, each associated with a specific stack, review the following additional configuration steps:

• You probably need to create a separate set of SNMP agent configuration files for each SNMP agent that you are going to start.

• If you want to start SNMP subagents that connect to the agent using a z/OS UNIX path name, then you need to perform the following tasks:
  – Define a unique path name for each stack.
  – Specify this path name on the SNMP agent -s start parameter.

    See OSNMPD parameters in z/OS Communications Server: IP Configuration Reference for more information about this parameter.

All of the z/OS Communications Server SNMP subagents connect to the agent using a z/OS UNIX path name.

Start the SNMP agent
The SNMP agent (OSNMPD) runs in a separate address space that executes load module EZASNMPD. OSNMPD can be started with or without parameters. When starting OSNMPD from MVS, add the parameters to the PARM= keyword on the EXEC statement of the OSNMPD cataloged procedure. When starting OSNMPD from z/OS UNIX, specify the parameters on the osnmpd command. See OSNMPD parameters in z/OS Communications Server: IP Configuration Reference for the command syntax.

For information about starting the SNMP agent in a common INET (CINET) environment, see “Common INET considerations” on page 1224.
If the SNMP agent encounters any errors processing its configuration files, error messages are written to the syslog daemon, not to the console.

Sample JCL procedure for starting OSNMPD from MVS

Update cataloged procedure OSNMPD by copying the sample in SEZAINST(OSNMPDPR) to your system or recognized PROCLIB. Change the data set names as required to suit your local configuration. The OSNMPD address space requires access to the z/OS XL C/C++ run-time library data sets during execution.

You can pass parameters to the agent on the PARMS= keyword on the EXEC statement of the OSNMPD cataloged procedure. See z/OS Communications Server: IP Configuration Reference for the command syntax and parameter information. You can specify any agent parameters that you want, as shown in the following example:

```
//OSNMPD EXEC PGM=EZASNMPD,REGION=4096K,TIME=NOLIMIT,
// PARM='-c abc -d 255 -p 761'
```

In this example, the agent will use port 761 to accept requests, community name abc will be added to the list of community names supported by the agent, and all agent traces will be activated. For more information on tracing, see the z/OS Communications Server: IP Diagnosis Guide.

Starting OSNMPD from z/OS UNIX

To run the SNMP agent in background, you must add an ampersand (&) to the command and the issuer of the command must be in z/OS UNIX superuser mode. For a detailed explanation of the parameters, see z/OS Communications Server: IP Configuration Reference.

Any agent parameters that you want to specify can be added as shown in the following example:

```
osnmpd -c abc -d 255 -p 761```

In this example, the agent will use port 761 to accept requests, community name 'abc' will be added to the list of community names supported by the agent, and all agent traces will be activated. For more information on tracing, see z/OS Communications Server: IP Diagnosis Guide.

Step 2: Configure the SNMP commands

The two SNMP client applications provided with z/OS Communications Server are:

- **snmp** command in the z/OS shell
- SNMP command from the NetView environment

The SNMP command in the NetView environment requires the use of the NetView product. It supports SNMP version 1. The **snmp** command in the z/OS shell supports SNMP versions 1, 2, and 3. Depending on your requirements, you might decide to configure either or both of these clients, or to use an SNMP client on another platform.

Configure the z/OS UNIX snmp command
The z/OS UNIX `snmp` command is used to send SNMP requests to SNMP agents on local or remote hosts, or to receive SNMP traps or notifications. You can also use the synonym, `osnmp`, as the name of this command. The requests can be SNMPv1, SNMPv2c, or SNMPv3. For SNMPv2c and SNMPv3 requests, the OSNMP.CONF configuration file is required. The `winSNMPname` specified on an OSNMP.CONF statement can be used as the value of the `-h` parameter on the `snmp` command. For a detailed explanation of the parameters you can specify on the `snmp` command, see z/OS Communications Server: IP System Administrator’s Commands.

To configure the `snmp` command, perform the following tasks:

- The `snmp` command needs to be able to resolve the name of the host, on which the command is executing, to the host’s IP address. You can provide this information either by configuring a domain name server or by configuring local host files. For information about the search order used to locate local host files, see the local host tables entry in Table 36 on page 746. As part of its support for the SNMPv3 protocol, the command also uses this IP address when creating its SNMPv3 engineID value.

- Provide `snmp` configuration information
- Provide user MIB object information

**Provide snmp configuration information**

The OSNMP.CONF file is used to define target agents and, for SNMPv3, the security parameters to be used in sending requests to them.

The contents of the file, regardless of location, are the same. Only the first file found is used. A sample of this file is installed as file `/usr/lpp/tcpip/samples/snmpv2.conf`. This sample should be copied and modified for your installation. See z/OS Communications Server: IP Configuration Reference for more information.

**Examples**

- Example 1:
  
  The following entry defines an SNMPv2c node for `snmp`:

  | mvs1   | 9.67.113.79 snmpv2c |

  where `mvs1` is the name used with the `-h` parameter on the `snmp` command and `9.67.113.79` is the IP address of the SNMPv2c agent.

- Example 2:

  The following entry defines an SNMPv3 node:

  | v3mak  | 127.0.0.1 snmpv3 u1 - - AuthNoPriv HMAC-MD5 7a3e34265e0e829f27d8b4235ecfa987 - - |

Figure 147. Configuration files for `snmp`
where \textit{v3mak} is the name used on the -h parameter of the \texttt{snmp} command. An SNMP request sent using this entry uses USM user name \textit{u1} using HMAC-MD5 authentication but no encryption.

- **Example 3:**
The following entry defines an SNMPv3 node. The needed authentication and privacy keys will be generated from the password \textit{u6password}.

```plaintext
v3sap    127.0.0.1 snmpv3 u6 u6password - AuthNoPriv HMAC-SHA - -
```

The USM user is \textit{u6}. The authentication protocol is HMAC-SHA, and no encryption is used.

- **Example 4:**
The following entry defines an SNMPv3 node:

```plaintext
v3mpk_ipv6 ::1 snmpv3 u1 - - AuthPriv HMAC-MD5 7a3e34265e0e029f27d8b4235ecfa987 DES eac82a9d9fe90eca7911fdcab0deae
```

where \textit{v3mpk_ipv6} is the name used on the -h parameter of the \texttt{snmp} command. An SNMP request sent using this entry uses USM user name \textit{u1} using HMAC-MD5 authentication and CBC 56-bit DES encryption.

**Provide MIB object information in MIBS.DATA**

Like other SNMP managers, when you enter the z/OS UNIX \texttt{snmp} command you can specify the object identifier (OID) of the MIB object whose value you want to retrieve. If the MIB object is supported by one of Communication Server's SNMP functions, you can also use the MIB object textual name on the z/OS UNIX \texttt{snmp} command, instead of the object identifier. All the MIB objects supported by Communications Server functions are listed in the MIB objects appendix in z/OS Communications Server: IP System Administrator's Commands.

For example, to retrieve the SNMP agent sysUpTime MIB object, you can enter either of the following commands:

```plaintext
- \texttt{snmp -v get sysUpTime.0}
  sysUpTime.0 = 289700
- \texttt{snmp -v get 1.3.6.1.2.1.1.3.0}
  sysUpTime.0 = 292700
```

The 1.3.6.1.2.1.1.3 value is the OID for the sysUpTime MIB object.

If you have user-defined MIB objects or MIB objects from other products, and you want to use the textual names for these MIB objects on the z/OS UNIX \texttt{snmp} command, you can define these objects to the \texttt{snmp} command using the MIBS.DATA file. A sample of the MIBS.DATA file is installed as file `/usr/lpp/tcpip/samples/mibs.data`. Copy this sample and modify it for your installation. For the search order used to locate the MIBS.DATA file, see “Understanding search orders of configuration information” on page 13.

If other products provide files using MIBS.DATA syntax, append the statements from their files to your MIBS.DATA file so that these statements are accessible to the \texttt{snmp} command. For example, the IBM OSA-Express Direct subagent provides a file in MIBS.DATA syntax so that the textual names of its OSA-Express management data can be used with the z/OS UNIX \texttt{snmp} command. For information about how to obtain this file, see z Systems: Open Systems Adapter-Express Customer's Guide and Reference.

**MIBS.DATA statement syntax**

The format of a statement in the MIBS.DATA file is:

```plaintext
character_object_name object_identifier object_type
```

See z/OS Communications Server: IP Configuration Reference for more information about syntax.

**Configure the NetView SNMP command**
The SNMP command in the NetView environment can be used to send SNMP version 1 requests to SNMP agents on either local or remote hosts. The SNMP command requires the command processor itself, the SNMPiUCV task for inter-address space communication, and the SNMP query engine, which creates the packets sent to the SNMP agent. The NetView SNMP command and the SNMP query engine support only community-based security.

**Configure the SNMP query engine**

Update the SNMPQE cataloged procedure by copying the sample in SEZAINST(SNMPPROC) to your system or recognized PROCLIB. Specify SNMP parameters and change the data set names as required to suit your local configuration. The SNMPQE address space requires access to the z/OS XL C/C++ run-time library data sets during execution.

The SNMP query engine (SQESERV) needs access to the hlq.MIBDESC.DATA data set for the MIB variable descriptions. You can find a sample of this data set in SEZAINST(MIBDESC).

**MIBDESC.DATA data set**

The MIBDESC.DATA data set defines the short names for MIB variables. Short names are the character representation for the ASN.1 variable names. For example, sysUpTime is the short name for 1.3.6.1.2.1.1.3.0 (the MIB variable that stores the time since the SNMP agent was last restarted). Short names are generally shown as a combination of upper and lowercase characters, though SNMP on z/OS Communications Server ignores these case distinctions. Variable names must always be in ASN.1 language when they are sent to an SNMP agent. You can always use ASN.1 language to specify the variable names in an enterprise-specific tree (assuming that the agent supports them). You can use these short names to specify the MIB variables.

When you issue an SNMP GET, GETNEXT, or SET command, and specify the variable name in ASN.1 notation, the SNMP Query Engine uses that name and sends it in the SNMP packet to the agent. When you issue an SNMP GET, GETNEXT, or SET command, and specify the short name for the variable (for example, sysDescr), the SNMP Query Engine looks for that name in the MIBDESC.DATA data set and uses the ASN.1 name specified in the data set when it sends the SNMP packet to the agent.

The SNMPQE address space must be able to access the MIBDESC.DATA data set.

You can change the short names in the MIBDESC.DATA data set to the equivalent in your national language. You can also leave the current names and add the equivalent names in your national language. However, the SNMP MIBVNAME function returns only the first entry found in the data set that satisfies the search. In addition, all enterprise-specific variables used by hosts in your network should be added to this data set.
Entries in the data set do not need to be in a specific sequence. Each name starts on a new line. The following entry shows the line format.

<table>
<thead>
<tr>
<th>short_name</th>
<th>asn.1_name</th>
<th>type</th>
<th>time_to_live</th>
</tr>
</thead>
</table>

Each variable on the line is separated by either one or more spaces or tabs. An asterisk (*) in column 1 indicates that the line is a comment line.

The following sample is a MIBDESC.DATA line with a sysDescr variable translated in Dutch and a few enterprise variables added (in this example, company ABC received 1.3.6.1.4.1.42 as the ASN.1 number for their enterprise):

<p>| <em>----------</em> | <em>----------</em> | <em>----------</em> | <em>----------</em> |</p>
<table>
<thead>
<tr>
<th>MIB Variable name</th>
<th>ASN.1 notation</th>
<th>Type</th>
<th>TTL</th>
</tr>
</thead>
<tbody>
<tr>
<td>Following is Dutch name for sysDescr</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>systeemBeschrijving</td>
<td>1.3.6.1.2.1.1.1.</td>
<td>display</td>
<td>900</td>
</tr>
<tr>
<td>sysDescr</td>
<td>1.3.6.1.2.1.1.1.</td>
<td>display</td>
<td>900</td>
</tr>
<tr>
<td>...</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

* Following are Enterprise-Specific variables for company ABC
| | | |
| ABCInfoPhone | 1.3.6.1.4.1.42.1.1 | display | 900 |
| ABCInfoAddress | 1.3.6.1.4.1.42.1.2 | display | 900 |

The TTL field contains the number of seconds that a variable lives in the Query Engine’s internal cache. If there are multiple requests for the same variable within the TTL period, the variable value is obtained from the cache, and unnecessary network traffic is avoided.

You can define multiple short names or text names for the same variable, as shown with the Dutch translation of the sysDescr variable. In this case, the SNMP Query Engine returns the first value in the table on an SNMP MIBVNAME request. In the previous example, the SNMP Query Engine would return systeemBeschrijving and not sysDescr. The name returned is in mixed case.

When the SNMP Query Engine receives a short name or text name in a GET, GETNEXT, or SET request, it compares the name against the entries in the MIBDESC.DATA data set. This comparison is not case-sensitive. For example, a request for SYSDESCR, SysDescr, or sysDescr matches the sysDescr entry with an ASN.1 notation of 1.3.6.1.2.1.1.1.

When the SNMP Query Engine receives an SNMP response, it looks up the variable in the MIBDESC.DATA table Type field for information about translating the value into displayable characters. The information contained in the Type field is case-sensitive and must be specified in lowercase.

**Note:** If you are using SNMP to receive response or trap PDUs which contain enterprise-specific variables, the variables must be added to the MIBDESC.DATA data set.

**Specifying the SNMPEQE parameters**

The SQESERV module can be configured to start without parameters or you can add any of the following parameters to PARMS=' in the PROC statement of the SNMPEQE cataloged procedure. For example,

```
//SNMPEQE   PROC MODULE=SNMPEQE,PARMS='-h MVSA'
```

See z/OS Communications Server: IP Configuration Reference for the command syntax.

See z/OS Communications Server: IP Diagnosis Guide for more information on tracing.

**Setting up authorization for SNMPEQE**

To create RAW sockets necessary for SNMP PING requests, the user ID associated with the SNMPEQE started task must have superuser authority (z/OS UNIX UID of 0), or must be permitted to become a superuser by having READ access to the BPX.SUPERUSER resource in the FACILITY class.

**Configure NetView as an SNMP monitor**

To configure the NetView interface as an SNMP monitor, perform each of the following tasks:
• Configure for SNMPIUCV
• Configure for the SNMP command processor
• Configure for the SNMP messages
• Update the SNMP initialization parameters

**Configure for SNMPIUCV**

SNMPIUCV is the NetView optional task that handles IUCV communication between the NetView program and the SNMP query engine. SNMPIUCV is in the SEZADSIL data set.

Add the following TASK statement for SNMPIUCV to the DSIDMN member of the data set specified by the DSIPARM DD statement in the NetView start procedure.

```
TASK MOD=SNMPIUCV,TSKID=SNMPIUCV,PRI=5,INIT=Y
```

This statement causes SNMPIUCV to start automatically when the NetView program is started.

If you specify INIT=N instead of INIT=Y in the TASK statement for SNMPIUCV, a NetView operator can start the SNMPIUCV task by entering the following command:

```
START TASK=SNMPIUCV
```

The SNMPIUCV task tries to connect through IUCV to the SNMP query engine. If this fails, it tries the connect again as specified by the SNMPQERT keyword in the SNMPARMS member of the SEZADSIP data set. The default is every 60 seconds.

**Configure for the SNMP command processor**

SNMP is the command processor that allows NetView operators and CLISTs to issue SNMP commands. SNMP is in the SEZADSIL data set. This data set should be concatenated to the STEPLIB DD statement in the NetView start procedure.

Add the following statement to the DSICMD member of the data set specified by the DSIPARM DD statement in the NetView start procedure.

```
SNMP CMDMDL MOD=SNMP,ECHO=Y,TYPE=R,RES=Y
```

After the SNMPIUCV task is started, you can issue the SNMP command. The SNMP command passes a request to the SNMPIUCV task to forward to SNMPQE. The return code represents a request number that is associated with the request. The responses are returned asynchronously and contain this request number. The operator or CLIST must use the request number to correlate the response to the request.

**Configure for the SNMP messages**

The NetView SNMP messages are in the SEZADSIM data set as DSISNMnn, where nn is the number of the member. The valid message members are DSISNM00 through DSISNM05, DSISNM10, DSISNM12, and DSISNM99. The data set containing these members should be added to the DSIMSG DD statement in the NetView start procedure.

**Update the SNMP initialization parameters**

SNMPIUCV reads the SNMPARMS member in the SEZADSIP data set at startup. This data set contains the initialization parameters for SNMP. The data set containing SNMPARMS should be added to the DSIPARM DD statement in the NetView startup procedure. See z/OS Communications Server: IP Configuration Reference for detailed information for the SNMP parameter data set (SNMPARMS).

---

**Step 3: Configure the SNMP subagents**

There are several SNMP subagents shipped with z/OS Communications Server:
• The TCP/IP subagent reports information about the TCP/IP stack. For details on configuring this subagent, see “TCP/IP subagent configuration” on page 1231.

• The OMPROUTE subagent reports information specific to OSPF. The ROUTESA_CONFIG statement is used in the OMPROUTE configuration file to configure the OMPROUTE subagent. For details on ROUTESA_CONFIG, see z/OS Communications Server: IP Configuration Reference.

• The Network SLAPM2 subagent reports information about defined policies and performance statistics related to traffic using those policies. For configuration information about the Network SLAPM2 subagent, see Chapter 15, “Quality of service,” on page 803.

• The TN3270E Telnet subagent reports information about TN3270E Telnet server connections and monitoring values. For information on the TNSACONFIG statement and the parameters needed to start the TN3270E Telnet subagent, see z/OS Communications Server: IP Configuration Reference.

• The OSA-Express Direct SNMP subagent is also shipped with z/OS CS but is supported by the System z OSA Support Group. The OSA-Express Direct SNMP subagent and the OSA MIB provided by the System z OSA Support Group can be used with Communications Server SNMP support to provide SNMP management data for some OSA adapters. For details regarding the OSA-Express Direct SNMP subagent and OSA MIB, see z Systems: Open Systems Adapter-Express Customer’s Guide and Reference.

These subagents use the stack's IPv4 primary interface IP address when connecting to the SNMP agent. The IPv4 primary interface IP address is either the first IPv4 IP address specified in the HOME profile statement, or the IP address of the IPv4 interface specified on a PRIMARYINTERFACE profile statement. If the subagents cannot obtain the IPv4 primary interface IP address, they will use the IPv4 loopback IP address, 127.0.0.1, to connect to the agent. For information on using the IPv4 primary interface IP address and a community name to permit the subagents to connect to the SNMP agent, see “Provide community name information” on page 1217 or “Provide community-based and user-based security and notification destination information” on page 1219.

TCP/IP subagent configuration

There are two statements in the profile data set used to configure the TCP/IP subagent, the SACONFIG and ITRACE statements.

• SACONFIG

Use the SACONFIG statement to configure the subagent. The SACONFIG parameters determine whether or not the subagent is automatically started at TCP/IP initialization, what port number to use to contact the agent, and other configuration values. For a detailed explanation of this statement, see z/OS Communications Server: IP Configuration Reference.

• ITRACE

Use the ITRACE statement to determine what trace information, if any, should be recorded by the subagent. For a detailed explanation of this statement, see z/OS Communications Server: IP Configuration Reference.

Step 4: Configure the Open Systems Adapter support

The TCP/IP subagent can retrieve SNMP management data from the Open Systems Adapter Support Facility (OSA/SF) for several OSA adapters.

The OSA product also provides an SNMP subagent, the OSA-Express Direct subagent, that supports management data for OSA-Express adapters. You can use the OSA-Express Direct subagent with Communications Server SNMP support to retrieve the management data. Use the OSA-Express Direct subagent for OSA management data, rather than the TCP/IP subagent, for the following reasons:

• The OSA-Express Direct subagent communicates directly with the OSA-Express adapters and does not require the OSA/SF and IOASNMP applications.

• The OSA-Express Direct subagent supports all OSA-Express adapters. The TCP/IP subagent does not support OSA-Express3 or later adapters.
For more information about the management data provided by the OSA-Express Direct subagent, see z Systems: Open Systems Adapter-Express Customer’s Guide and Reference.

The TCP/IP subagent supports management data for the following OSA-Express2 adapters:

• Ethernet management data is supported for Gigabit Ethernet or QDIO Fast Ethernet adapters.
• Tables of OSA-Express management data are supported for Gigabit Ethernet or Fast Ethernet adapters.

Restriction: The TCP/IP subagent does not support OSA-Express3 or later adapters.

The TCP/IP subagent retrieves the data using the OSA/SF components IOAOSASF (OSA/SF application) and IOASNMP (OSA/SF socket application). For more information on these components, see “OSA/SF prerequisites” on page 1233. Specifying the SACONFIG profile statement, with the OSAENABLED and OSASF parameters, in the TCP/IP profile data set causes the TCP/IP subagent to try to connect to the OSA/SF socket application, IOASNMP, using the TCP protocol and the port number specified on the OSASF parameter. If the subagent connects successfully, the following message is issued:

**EZ3218I SNMP SUBAGENT: CONNECTED TO OSA/SF**

Because of timing considerations, the TCP/IP subagent might not be able to connect to IOASNMP at initialization. If this occurs, the subagent will attempt to connect when the first request for OSA MIB data is received. Therefore, the EZ3218I message might not always be issued during subagent initialization.

When retrieving management data from the OSA adapters, the TCP/IP subagent sends a request to IOASNMP for the data, passing the adapter's portname as an identifier. The portname is obtained from the DEVICE and LINK profile statements used to define the adapter to the TCP/IP stack. The IOASNMP socket application uses APPC to pass the request to the OSA/SF application. The OSA/SF application then retrieves the data from the adapter and returns it to IOASNMP. IOASNMP uses its TCP connection to the TCP/IP subagent to return the data to the subagent. If this configuration is active and either the IOASNMP application or the TCP/IP subagent terminates, the subagent will issue the following message:

**EZ3219I SNMP SUBAGENT: DISCONNECTED FROM OSA/SF**

To obtain the management data, the adapters must be defined to the TCP/IP stack where the subagent is active, through DEVICE and LINK statements in the TCP/IP profile.

• To retrieve Ethernet management data, the OSA-Express adapter must be defined as an MPCIPA Ethernet link.
• To retrieve OSA-Express management data, the adapters must be defined as the following TCP/IP device/link types:
  -- MPCIPA link for Gigabit Ethernet
  -- MPCIPA or LCS Ethernet link for Fast Ethernet

If the port name is manually configured at the adapter, then management data can be retrieved from the adapter even if it is not active and not in use by any TCP/IP stack or by VTAM. If the port name is dynamically configured (e.g. MPCIPA links), then the adapter has to be active to some TCP/IP stack to retrieve the management data.

Current support consists of:

• OSA-Express Channel and Performance tables from the IBM MVS Enterprise-Specific MIB for OSA-Express Gigabit Ethernet and Fast Ethernet adapters. The performance MIB object values in the ibmMvsOsaExpChannelTable, and all of the MIB object values in the ibmMvsOsaExpPerfTable, are only available from OSA-Express adapters on which a microcode level of 1.31 or later is installed, and that are active on a System z processor.
• OSA-Express Ethernet Port table from the IBM MVS Enterprise-Specific MIB for OSA-Express Gigabit Ethernet and Fast Ethernet adapters.
• OSA-Express Ethernet SNA table from the IBM MVS Enterprise-Specific MIB for OSA-Express Fast Ethernet adapters.
• dot3StatsTable from EtherLike-MIB in RFC2665 for OSA-Express Gigabit Ethernet and QDIO Fast Ethernet adapters.

OSA/SF prerequisites

The TCP/IP subagent provided by z/OS Communications Server will connect to OSA/SF to obtain management data. For a subagent to establish a connection to OSA/SF, two OSA/SF components must be started:

• IOAOSASF

IOAOSASF is a sample JCL procedure that can be used to start the main OSA/SF address space. The sample has a job name of OSASF1.

• IOASNMP

IOASNMP is a sample JCL procedure that starts the OSA/SF-provided z/OS UNIX socket application that interconnects the TCP/IP subagent with OSASF1.

These sample procedures and all entities that they call are provided with OSA/SF. For a detailed explanation of how to set up OSA/SF on your MVS system, see z Systems: Open Systems Adapter-Express Customer’s Guide and Reference. The primary purpose of OSA/SF is to manage OSA Adapters. It has been extended to support OSA management via SNMP. An instance of IOAOSASF, IOASNMP, the TCP/IP stack, the TCP/IP subagent, and the SNMP agent must be started on every MVS image where OSA management support is needed.

The recommended startup order is:

1. Start IOAOSASF and wait until it completely initializes. IOAOSASF must be started before IOASNMP.
2. Include OSNMPD (the CS SNMP agent) and IOASNMP on the AUTOLOG statement for your TCP/IP stack. This ensures that they will be started by autolog processing when TCP/IP is started. For additional profile statement requirements, see “Required TCP/IP profile statements” on page 1233. Start the TCP/IP stack.

On an MVS image only a single instance of either IOAOSASF or IOASNMP can (or should) be started. An attempt to start multiple copies of IOAOSASF will be rejected. Starting multiple copies of IOASNMP will yield unpredictable results.

Ensure that OSA/SF is at Version 2 Release 1 level or higher with the OSA/SF APAR OW45237 applied.

Required TCP/IP profile statements

For a detailed description of the statements mentioned here, see z/OS Communications Server: IP Configuration Reference. The following TCP/IP profile statements must be updated for OSA management support:

• SACONFIG

On the SACONFIG statement, OSA Management support must be enabled by specifying OSAENABLED. Omission of OSAENABLED when TCP/IP is started will result in no OSA management support. The SACONFIG statement controls the operation of the subagent that runs in a TCP/IP address space as a separate task.

The OSASF parameter specifies which port IOASNMP should use to Listen for connections from subagents to OSA/SF. For an explanation of the usage of this parameter when starting multiple TCP/IP instances, see “Subagent connection to OSA/SF when there are multiple TCP/IP instances” on page 1234. It is recommended that the OSASF port be reserved by also specifying it on a PORT statement.

For example:

SACONFIG OSAENABLED OSASF 721

• PORT

Prereserve the port to be used in communication with OSA/SF.
For example:

```
PORT
721 TCP IOASNMP ; OSA/SF TCP/IP Communications
```

In this example, because IOASNMP runs as a z/OS UNIX application, the port could have been reserved for z/OS UNIX. Review the /etc/services file to ensure that there are no port conflicts.

- **DEVICE and LINK**

  Provide DEVICE and LINK statements for any OSA-Express Ethernet adapter for which you want SNMP Ethernet management data. For example:

  ```
  DEVICE portname MPCIPA NONROUTER
  LINK linkName IPAQENET portname
  ```

**Subagent connection to OSA/SF when there are multiple TCP/IP instances**

When multiple z/OS Communications Server instances are active in the same MVS image, only one of the TCP/IP instances is connected to IOASNMP. For a TCP/IP instance to connect to IOASNMP, the OSASF parameter must be specified on the SACONFIG profile statement.

IOASNMP connects to a TCP/IP instance and acts as a server, receiving connections from those TCP/IP subagents where OSAENABLED was specified on the SACONFIG Profile statement. The result is that all these subagents connect through the same TCP/IP to IOASNMP in order to retrieve OSA information from OSA/SF. For a depiction of this process, see Figure 149 on page 1234.

![Figure 149. Subagent connection to OSA/SF](image)

If IOASNMP loses its connection to TCP/IP it terminates and needs to be restarted.

If the currently connected TCP/IP terminates, IOASNMP will attempt to connect to another TCP/IP instance for which the OSASF parameter was specified on the SACONFIG Profile statement, using the port number specified for the OSASF parameter. The subagents will also attempt to reconnect to OSA/SF via IOASNMP using this same OSASF port number. For this reason it is recommended that the same OSASF port number be used on the SACONFIG statement of every TCP/IP instance where the OSASF parameter is specified.

Whenever a socket error occurs on the OSA/SF socket, the connected subagents will issue the following message:

```
EZZ3219I SNMP SUBAGENT: DISCONNECTED FROM OSA/SF
```
Step 5: Configure the trap forwarder daemon

Most SNMPv1 agents forward traps to port 162. If a manager needs to listen for these traps, it has to bind to port 162 and listen for it. When a manager has already issued a bind it is impossible for another manager to listen for the same traps. The Trap Forwarder daemon eliminates this problem by listening for traps on port 162 and forwarding them to all the configured managers.

You can configure the Trap Forwarder daemon to receive a trap on a specified port and forward it to multiple other ports on the same host and on different hosts. This will allow multiple SNMP managers on z/OS to be able to receive all the traps sent to one port.

To configure the Trap Forwarder daemon, perform the following tasks:

1. Provide PROFILE.TCPIP statements.
2. Provide Trap Forwarder configuration.
3. Start the Trap Forwarder daemon (TRAPFWD).

Provide PROFILE.TCPIP statements

Add or update the following PORT configuration statements in hlq.PROFILE.TCPIP.

The default port used by the trap forwarder daemon to receive trap datagrams is UDP port 162. If you want to ensure that no other application uses this port, you must specify the following PORT statement:

| PORT 162 | UDP | TRAPFWD | Trap Forwarder daemon |

If the daemon will be started from the z/OS shell, reserve the port for z/OS UNIX by changing OMVS instead of TRAPFWD. Note that by doing so, the snmp command could make use of the port if it is started (with the trap option) before TRAPFWD is started.

Provide trap forwarder configuration information

The TRAPFWD.CONF file defines the configuration parameters for trapfwd daemon.

A sample of the TRAPFWD.CONF is shown below:

```
# A sample configuration file for trapfwd
#
# Syntax : ip_address/host_name port_number option
#
9.67.113.79       1064 ADD_RECVFROM_INFO
myHost             1066
myHost             1067 ADD_RECVFROM_INFO
myHost             1099
9.67.35.37         1064 ADD_RECVFROM_INFO
-                  1065
-                  1068 ADD_RECVFROM_INFO
12ab::2            1069
```

For more information about the statement syntax, see z/OS Communications Server: IP Configuration Reference.

Starting and stopping the trap forwarder daemon

The Trap Forwarder daemon can be started from the z/OS UNIX shell or from the MVS console.
Starting the trap forwarder daemon from z/OS UNIX

This example starts the Trap Forwarder daemon on the standard port (port 162).

```bash
# trapfwd
```

This example starts the Trap Forwarder daemon on a particular port (port 5062).

```bash
# trapfwd -p 5062
```

Starting the trap forwarder daemon from an MVS console

Update cataloged procedure TRAPFWD by copying the sample in SEZAINST(EZASNTRA) to your system. See z/OS Communications Server: IP Configuration Reference for more information about this cataloged procedure.

Stopping the trap forwarder daemon

From MVS:

```bash
P TRAPFWD
```

If TRAPFWD was started from a cataloged procedure, `procname` is the member name of that procedure. If TRAPFWD was started from the z/OS shell, `procname` is based on the `userid`. If the `userid` is 8 characters long, the `procname` is the `userid`. If the `userid` is less than 8 characters long, the `procname` is `useridX`, where `X` is the sequence number set by the system. To determine the sequence number issue `d omvs u=userid` from the console. This will show the programs running under the user ID.

From UNIX:

```bash
kill < pid >
```

Issue the `kill` command to the process ID (PID) associated with TRAPFWD. To find the PID issue the `ps -ef` command from the z/OS shell.

Tracing

The MODIFY command can be used to display the existing tracing level and also to change the tracing level.

The following example sets the trace level of the Trap Forwarder Daemon to 1.

```bash
MODIFY TRAPFWD,TRACE,LEVEL=1
```

The following example displays the level of tracing set for the Trap Forwarder Daemon.

```bash
MODIFY TRAPFWD,TRACE,QUERY
```

See z/OS Communications Server: IP Configuration Reference for more information about syntax.

Dynamically refreshing configuration

The MODIFY command can be used to dynamically refresh the configuration information. When this is done, the old configuration information is discarded completely. The configuration file is read again and the daemon is initialized.

The following example refreshes the configuration by reading the configuration file.

```bash
MODIFY TRAPFWD,REFRESH
```

See z/OS Communications Server: IP Configuration Reference for more information about syntax.
Chapter 24. Remote print server

Read “Understanding search orders of configuration information” on page 13. It covers important information about data set naming and search sequences.

The remote print server supports the line print daemon (LPD) and allows you to print on JES controlled printers from any host in your IP network that implements the line print client functions. These client functions are invoked with the LPR command. LPR is available as a TSO command, and the LPD server is implemented as a started z/OS task.

See z/OS Communications Server: IP System Administrator’s Commands for information on starting and stopping the TCP/IP print server (LPD). When LPD is stopped by the MVS operator with the P procname command, LPD will terminate any TCP/IP connections currently transferring data. Before ending, LPD will finish spooling to JES any print jobs that it has received and is currently spooling. JES will handle these jobs after LPD ends.

This topic describes how to configure the LPD server. To operate the LPD server after it is running, see z/OS Communications Server: IP Configuration Reference.

The LPD server uses the Pascal socket API, so VMCF must be started for the server to successfully initialize. If VMCF is not started, message EZY1980E will be issued and the server will terminate.

Configuring the Remote Print Server

Procedure

Perform the following steps to configure the Remote Print Server:

1. Specify AUTOLOG and PORT statements in PROFILE.TCPIP.
2. Update the LPD server cataloged procedure.
3. Update the LPD server configuration data set.
4. Create a banner page (optional).

Results

For information about operating and controlling the LPD server, see z/OS Communications Server: IP Configuration Reference.

Step 1: Configuring PROFILE.TCPIP for LPD

If you want the LPD server started automatically when the TCPIP address space is started, include the name of the member containing the LPD server cataloged procedure in the AUTOLOG list in hlq.PROFILE.TCPIP. For example:

```
AUTOLOG
LPSERVE
ENDAUTOLOG
```

To ensure that port TCP 515 is reserved for the LPD server, also add the name of the member containing the LPD cataloged procedure to the PORT statement in hlq.PROFILE.TCPIP. For example:

```
PORT
515 TCP LPSERVE
```

See the z/OS Communications Server: IP Configuration Reference for more information about the AUTOLOG and PORT statements.
Step 2: Updating the LPD server cataloged procedure

Update the LPD server cataloged procedure to suit your local configuration by copying the sample to your system or recognized PROCLIB from SEZAINST(LPSPROC) and modifying the sample. Specify LPD parameters, and change the data set names as required. See “Specifying LPD server parameters” on page 1238 for more information on the LPD server parameters.

Specifying LPD server parameters

The system parameters required by the LPD server are passed by the PARM option on the EXEC statement of the LPD cataloged procedure. Update the following parameters as required.

LPDDATA='data_set_name'

Specifies the fully qualified name of the data set containing the LPD configuration statements. This data set can be sequential or a member of a PDS.

LPDPRFX='PREFIX your_prefix'

Specifies the high-level qualifier to be used for temporary data sets created by the LPD server. Include both the PREFIX keyword and your qualifier in the quoted string. The qualifier may be up to 26 characters. If it is blank, the default is the procedure name. The LPD task requires the authority to create and modify data sets with this prefix.

DIAG='options'

Specifies any of the following diagnostic options in a quoted string of keywords separated by blanks. For example, DIAG='VERSION TRACE'

VERSION

Displays the version number.

TYPE

Activates high-level trace facility in the LPD server. Significant events, such as the receipt of a job for printing, are recorded in the //SYSOUT DD data set specified in your LPD server cataloged procedure.

TRACE

Causes a detailed trace of activities within the LPD server to record in the //SYSOUT DD data set specified in your LPD server cataloged procedure. The detailed tracing can also be activated with the DEBUG statement in the LPD server configuration data set and with the TRACE command of the SMSG interface.

Note: The JCL PARM= statement has a limit of 100 characters.

Configuring LPDDATA

Use a DD card that requires the LPD configuration file to be in a data set.

//SYSLPDD DD DISP=SHR, DSN=TCPIP.SEZAINST(LPDDATA)

Using this example, the DD card must be specified as SYSLPDD, but the data set name can be any valid data set name with a member specified up to 44 characters.

To use the DD card method, you must comment out or remove the LPDDATA= parameter from the PROC statement and remove the "&LPDDATA" PARM from the LPD EXEC statement.

Note: The search order for the configuration file is:

1. LPDDATA= on the PARM= statement
2. //SYSLPDD DD statement
3. hlq.LPD.CONFIG

If both the LPDDATA= statement on the PARM= statement and the //SYSLPDD DD statement are specified, the data set name specified on LPDDATA= is used.
The LPD server does not limit the number of print jobs it handles per connection. This can cause a memory abend to occur if too many print jobs are sent in one connection. Certain LPR clients, such as SUN UNIX, are set up to send multiple jobs in one connection. It is recommended that the LPD start procedure be started with a region size of 6M and the LPR client send no more than 50 print jobs in one connection.

**Step 3: Updating the LPD server configuration data set**

The LPD configuration data set defines the local, NJE, and remote services (printers and punches) used by the LPD server. To update the LPD server configuration data set, copy the sample provided in SEZAINST(LPDDATA) and modify it to suit your installation. See z/OS Communications Server: IP Configuration Reference for more details.

- To define a printer or punch:
  - Include a SERVICE statement with the appropriate parameters for each printer or punch your are defining.
  - Specify the type of service with the LOCAL, NJE, or REMOTE parameter in the SERVICE statement.
  - For local or NJE services, include any of the optional parameters to further define the service: EXIT, FAILEDJOB, FILTERS, LINESIZE, PAGESIZE and RACF.
  - For remote services, specify the destination printer and host. Any additional specifications are defined on the remote system and are not necessary in the SERVICE statement.
- To turn on LPD server tracing, include the optional DEBUG statement.
- To authorize users for the SMSG interface, include the optional OBEY statement.
- Printer names cannot contain an at sign (@).

**Step 4: Creating a banner page (optional)**

LPBANNER is the name of the default program that is provided in executable form in the SEZATCP data set. This program is specified on the EXIT parameter in the SERVICE statement. LPBANNER prints a separator page that contains, in large letters, a banner stating “LPD BANNER”, the user ID, the job name, and the job class. Field headings of HOST, USER, JOB, and CLASS appear in smaller letters.

The sample exit LPBANNER uses machine carriage control and is designed to be used with the SERVICE PRINTER LOCAL or SERVICE PRINTER NJE statements. To use this sample exit, both SERVICE statements require a printed LINESIZE of 78 or greater. Banner pages are usually not used with the SERVICE PUNCH or SERVICE RECFMU statements; however, if you want to have banner pages (headers) for the SERVICE PUNCH or SERVICE RECFMU devices, a user created banner exit is required.

You can either use the executable form or copy and modify the sample source provided in SEZAINST(EZAAE04S) and SEZAINST(EZAAE04T) to create a banner. If you are changing the source to create your own banner, assemble and link-edit these data sets as reentrant. You can modify and use the following JCL to do this. Changing the ENTRY and NAME to something other than LPBANNER will avoid possible maintenance problems in the future.

```assembly
//ASMLNK JOB MSGLEVEL=(1,1),MSGCLASS=A,CLASS=A,REGION=1024K
//ASM1 EXEC PGM=ASMA90,PARM='OBJECT,XREF(FULL)'
//STEPLIB DD DISP=SHR,DSN=HLA.OSV1R4.SASMMOD1
/*/  ASSEMBLER  H
//SYSLIB DD DSN=tcpipl_h.lq.SEZACMAC,DISP=SHR
// DD DSN=SYS1.MACLIB,DISP=SHR
// DD DSN=SYS1.MODGEN,DISP=SHR
//SYSUT1 DD UNIT=SYSDA,SPACE=(CYL,(5,5)),DSN=&&SYSUT1
//SYSPUNCH DD DUMMY,DCB=BLKSIZE=800
//SYSPRINT DD SYSPRT=1
//SYSLIN DD DSN=&&OBJECT(EZAAE04S),DISP=(,PASS),UNIT=SYSDA,
// SPACE=(CYL,(5,5,1)),DCB=BLKSIZE=400
//SYSIN DD DSN=tcpipl_h.lq.SEZAINST(EZAAE04S),DISP=SHR
/*/  ASSEMBLER  H
//SYSLIB DD DSN=tcpipl_h.lq.SEZACMAC,DISP=SHR
// DD DSN=SYS1.MACLIB,DISP=SHR
```
//         DD DSN=SYS1.MODGEN,DISP=SHR
//SYSUT1   DD UNIT=SYSDA,SPACE=(CYL,(5,5)),DSN=&SYSUT1
//SYSPUNCH DD DUMMY,DCB=BLKSIZE=80
//SYSPRINT DD SYSOUT=A
//SYSLIN   DD DSN=&OBJECT(EZAAE04T),DISP=(OLD_PASS)
//SYSIN    DD DSN=tcpip_hlq.SEZAINST(EZAAE04T),DISP=SHR
/*
//LNK    EXEC PGM=IEWL,PARM='LIST,NCAL,RENT,LET'
//SYSPRINT DD SYSOUT=A
//SYSUT1   DD UNIT=SYSDA,SPACE=(CYL,(1,1))
//SYSLMOD  DD DSN=tcpip_hlq.SEZATCP,DISP=SHR
//AEZAMODS DD DSN=tcpip_hlq.AEZAMODS,DISP=SHR
//OBJECT   DD DSN=&OBJECT,DISP=(OLD,DELETE)
//SYSLIN   DD *
ORDER   EZBOECPR
INCLUDE AEZAMODS(EZBOECPR)

1240  z/OS Communications Server: IP Configuration Guide
Chapter 25. Remote procedure calls

This topic contains information to help you configure the following applications and interface:

- PORTMAP
- UNIX PORTMAP
- rpcbind
- NCS

**Restriction:** PORTMAP, UNIX PORTMAP, and rpcbind cannot be run concurrently, because all three applications listen on the well known /etc/services sunrpc port of 111. You must determine which server will service your RPC applications.

For information about rpcbind configuration and setup in a multilevel secure environment, see “z/OS UNIX rpcbind server” on page 192.

Read “Understanding search orders of configuration information” on page 13. It covers important information about data set naming and search sequences.

Steps for configuring the PORTMAP address space

The PORTMAP address space runs the Portmapper function. Portmapper is the software that supplies client programs with the port numbers of server programs.

**About this task**

Clients contact server programs by sending messages to port numbers where receiving processes receive the message. Because you make requests to the port number of a server rather than directly to a server program, client programs need a way to find the port number of the server programs that they want to call. Portmapper standardizes the way clients locate the port number of the server programs supported on a network.

**Procedure**

Perform the following steps to configure PORTMAP:

1. Specify AUTOLOG and PORT statements in hlq.PROFILE.TCPIP.
2. Configure security server (or RACF equivalent) items.
3. Update the PORTMAP cataloged procedure.
4. Define the data set for well-known procedure names.

**Step 1: Configuring PROFILE.TCPIP for PORTMAP**

If you want the PORTMAP server to start automatically when the TCPIP address space is started, you should include PORTMAP in the AUTOLOG statement in the hlq.PROFILE.TCPIP data set.

```
AUTOLOG
PORTMAP
ENDAUTOLOG
```

**Note:** If your system is using the Network File System (NFS) server, you must start the PORTMAP address space. See z/OS Network File System Guide and Reference for more information.
To ensure that port UDP 111 and TCP 111 are reserved for the PORTMAP server, also add the name of the member containing the PORTMAP cataloged procedure to the PORT statement in hlq.PROFILE.TCPIP:

```
PORT
111 UDP PORTMAP
111 TCP PORTMAP
```

See the z/OS Communications Server: IP Configuration Reference for more information about the AUTOLOG and PORT statements.

**Step 2: Configuring security server (or RACF equivalent) items**

The PORTMAP cataloged procedure assumes that the procedure has the authority to run as a started task. To ensure that the PORTMAP procedure has the appropriate security server access, enter the following commands as shown in SEZAINST(EZARACF):

```
ADDUSER PORTMAP DFLTGRP(OMVSGRP) OMVS(UID(0) HOME('/')) NOPASSWORD
RDEFINE STARTED PORTMAP.* STDATA(USER(PORTMAP))
SETROPTS RACLIST(STARTED) REFRESH
SETROPTS GENERIC(STARTED) REFRESH
```

**Step 3: Updating the PORTMAP cataloged procedure**

Update the PORTMAP cataloged procedure to suit your local conditions by copying the sample provided in SEZAINST(PORTPROC) to your system or recognized PROCLIB and modifying it to suit your local conditions. Change the data set names as required. See z/OS Communications Server: IP Configuration Reference for more details.

**Step 4: Defining the data set for well-known procedure names**

z/OS Communications Server includes a data set that contains a list of commonly used procedure names. This data set is used by the RPCINFO command to resolve remote program numbers into their equivalent program names.

To create the data set, copy SEZAINST(ETCRPC) to the default data set called hlq.ETC.RPC. If a user has a user_id.ETC.RPC data set defined, it takes precedence over the preceding data set.

Normally, you would not change this data set except to add a new application to the list. To add a new application, add a line that contains the following items:

- The program_name of the new application or procedure
- The program_number of the new application or procedure
- Any comments regarding the description of the program

The items are variable in format, each separated by a blank.

The SEZAINST(ETCRPC) data set contains the well-known procedure names. The following sample is the ETCRPC sample.

```
# z/OS Communications Server
# SMP/E distribution path: /usr/lpp/tcpip/samples/IBM/EZAOERPC
# SMP/E distribution path: SEZAINST(EZAEB01X)
#
# Licensed Materials - Property of IBM
# 5656-Z0S Copyright IBM Corp. 1996, 2015
# Status = CSV2R2
#
# Change Activity:
#
# Flag Reason  Release  Date  Origin  Description
# ------ ----- -------- -------- -------- -----------------------
# $Y1= D139012  R9BASEN  061011 staff : NFS information added
# $F1= RBAPPREM CSV1R11  080728 staff : Remove NDB
```
Starting the PORTMAP address space

If you did not include PORTMAP in the AUTOLOG statement, you can start PORTMAP with the START command. For example:

```
START PORTMAP
```

Steps for configuring the z/OS UNIX PORTMAP address space

The z/OS UNIX PORTMAP address space runs the Portmapper function.

**Procedure**

Perform the following steps to configure z/OS UNIX PORTMAP:

1. Specify PORT statements in `hlq.PROFILE.TCPIP`.
2. Update the PORTMAP cataloged procedure.

**Results**

**Step 1: Configuring PROFILE.TCPIP for UNIX PORTMAP**

If you want the PORTMAP server to start automatically when the TCPIP address space is started, you should include PORTMAP in the AUTOLOG statement in the `hlq.PROFILE.TCPIP` data set.

```
AUTOLOG
  PORTMAP  JOBNAME  PORTMAP1
ENDAUTOLOG
```
To ensure that port UDP 111 and TCP 111 are reserved for the z/OS UNIX PORTMAP server, add the z/OS UNIX PORTMAP server jobname to the PORT statement in hlq.PROFILE.TCPIP. If you use the sample cataloged procedure, PORTMAP, to start the z/OS UNIX PORTMAP server, the jobname is PORTMAP1:

```
PORT
111 UDP PORTMAP1 ; Portmapper Server
111 TCP PORTMAP1 ; Portmapper Server
```

See the z/OS Communications Server: IP Configuration Reference for more information about the PORT statement.

**Step 2: Updating the PORTMAP cataloged procedure**

Update the PORTMAP cataloged procedure to suit your local conditions by copying the sample provided in SEZAINST(OPORTPRC) to your system or recognized PROCLIB and modifying it to suit your local conditions. Change the data set names as required. See z/OS Communications Server: IP Configuration Reference for more details.

**Starting the PORTMAP address space**

There are two ways to start the portmapper as a z/OS UNIX socket application:

- From the z/OS shell
- As a started task

To start the portmapper from the z/OS shell, the user ID must be an authorized superuser. The authorized superuser ID can issue `oportmap &` to start the portmapper. For the authorization procedure, see z/OS UNIX System Services Planning.

You can also start PORTMAP as a started task with the START command as follows:

```
START PORTMAP
```

**Note:** If your system is using the Network File System (NFS) server, see z/OS Network File System Guide and Reference for more information.

**Steps for configuring the rpcbind address space**

The rpcbind software supplies client programs with the universal addresses of RPC server programs.

**Before you begin**

The z/OS rpcbind server supports the portmapper binding protocol (RPC Binding Protocol Version 2) as well as other RPC binding protocols. This means you can run rpcbind instead of portmapper. Portmapper and rpcbind cannot be run at the same time, because they both listen on /etc/services sunrpc port 111.

**About this task**

RPC server applications do not have well-known port numbers. Instead, they obtain an ephemeral port number, create a universal address, and register that address with rpcbind. Clients contact server programs by obtaining the universal address of the server from rpcbind, and sending messages to the universal address of the server.

**Procedure**

Perform the following steps to configure the rpcbind address space.

1. Configure the PROFILE.TCPIP data set for rpcbind.
2. Configure security server (or RACF equivalent) items.
3. Update the RPCBIND cataloged procedure.
4. Update the /etc/services file.
5. Configure SYS1.PARMLIB for rpcbind.

**Step 1: Configuring the PROFILE.TCPIP data set for rpcbind**

**Guideline:** The rpcbind server is a generic server, as described in “Generic servers in a CINET environment” on page 48.

- In a single stack environment, you can use the AUTOLOG statement to automatically start generic servers.
- In a multiple stack environment, it is not advisable to use the AUTOLOG statement to start generic servers. You can use an operations automation software package that IBM or other companies provide to automatically start generic servers.

If you want the rpcbind server to start automatically when the TCPIP address space is started, include rpcbind in the AUTOLOG statement in the PROFILE.TCPIP data set.

```plaintext
AUTOLOG
  RPCBIND JOBNAME RPCBIND1
ENDAUTOLOG
```

To ensure that port UDP 111 and TCP 111 is reserved for the rpcbind server, add the rpcbind server job name to the PORT statement in the PROFILE.TCPIP data set. If you use the sample cataloged procedure, RPCBIND, to start the rpcbind server, the job name is RPCBIND1.

```plaintext
PORT
  111 UDP RPCBIND1 ; rpcbind server
  111 TCP RPCBIND1 ; rpcbind server
```

If you start the rpcbind server from the z/OS UNIX shell, the job name is OMVS.

```plaintext
PORT
  111 UDP OMVS    ; rpcbind server OMVS
  111 TCP OMVS    ; rpcbind server OMVS
```

For more information about the PORT statement, see z/OS Communications Server: IP Configuration Reference.

**Step 2: Configuring security server (or RACF equivalent) items**

The RPCBIND cataloged procedure assumes that the procedure has the authority to run as a started task. To ensure that the RPCBIND procedure has the appropriate security server access, enter the following commands as shown in SEZAINST(EZARACF):

```plaintext
ADDUSER RPCBIND DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(0) HOME('/'))
RDEFINE STARTED RPCBIND.* STDATA(USER(RPCBIND))
SETOPTS RACLIST(STARTED) REFRESH
SETOPTS GENERIC(STARTED) REFRESH
```

You can define the SAF resource profile EZB.RPCBIND.sysname.rpcbindname.REGISTRY in the SERVAUTH class to control which users can register or deregister applications with rpcbind. You can use wildcards. For example, if you use wildcard values for sysname and rpcbindname, the profile name is as follows:

```plaintext
EZB.RPCBIND.*.*.REGISTRY
```

In this example, suppose the MVS system name is MVS000 and the RPCBIND catalogued procedure is used to start the rpcbind server. This procedure uses the job name RPCBIND. RPCBIND is fewer than 8 characters, so the rpcbindname is RPCBIND1, and the profile name is as follows:

```plaintext
EZB.RPCBIND.MVS000.RPCBIND1.REGISTRY
```

The profile EZB.RPCBIND.sysname.rpcbindname.REGISTRY is optional. If it is not defined, all users can register and deregister applications with rpcbind. If the profile is defined, only users granted at least READ access to this resource profile can register or deregister applications with rpcbind.
In this example, if your SAF security product is RACF and you want only the RPC server TRUESERV running under user ID TRUESERV to be able to register and deregister applications with rpcbind, you can use the following commands to define the profile EZB.RPCBIND.*.*.REGISTRY in the SERVAUTH class and grant TRUESERV read access to the profile:

```
RDEFINE SERVAUTH EZB.RPCBIND.*.*.REGISTRY UACC(NONE)
PERMIT EZB.RPCBIND.*.*.REGISTRY ID(TRUESERV) ACCESS(READ) CLASS(SERVAUTH)
```

Requirements for a multilevel secure environment:

- The profile EZB.RPCBIND.sysname.rpcbindname.REGISTRY is mandatory, and you must grant user IDs associated with trusted RPC servers at least READ access to this profile. For more information about running rpcbind in a multilevel secure environment, see “z/OS UNIX rpcbind server” on page 192.

- If the SAF FACILITY class resource profile BPX.POE is defined, and your installation directs target assistance calls to rpcbind, you must grant the user ID assigned to rpcbind at least READ access to this profile. For more information on target assistance, see z/OS Communications Server: IP Programmer’s Guide and Reference.

Tips:

- The target assistance RPCs PMAPPROC_CALLIT, RPCBPROC_CALLIT, RPCBPROC_BCAST, and RPCBPROC_INDIRECT are defined in RFC 1833 *(Binding Protocols for ONC RPC Version 2)*.

- The RPC library routines clnt_broadcast and pmap_rmtcall() issue a target assistance request on behalf of the caller.

- The rpcinfo utility issues a target assistance call when it is invoked with the -b option.

**Guideline:** If RPCBIND is the user ID assigned to the rpcbind server, you can use the following command to grant the user ID READ access to the profile:

```
PERMIT BPX.POE CLASS(FACILITY) ID(RPCBIND) ACCESS(READ)
```

Step 3: Updating the RPCBIND cataloged procedure

Update the RPCBIND cataloged procedure to suit your local conditions by copying the sample provided in SEZAINST(RPCBIND) to your system or recognized PROCLIB, and modifying it as necessary. Change the data set names as required. For further information, see “Starting the rpcbind address space” on page 1247. A copy of RPCBIND is also available in z/OS Communications Server: IP Configuration Reference.

Step 4: Updating the /etc/services file

Update /etc/services to ensure that the sunrpc service is reserved for TCP and UDP port 111:

```
sunrpc 111/tcp
sunrpc 111/udp
```

**Restriction:** If you change the sunrpc port, rpcinfo on that host will not be able to contact the rpcbind server.

Step 5: Configure SYS1.PARMLIB for rpcbind

The rpcbind server uses semaphore sets and shared memory segments. Inspect your BPXPRMxx member in SYS1.PARMLIB and verify that the following statements are configured such that rpcbind will be able to obtain three shared memory segments of one page each, and three semaphore sets:

```
IPC$SMMPAGES
IPC$SMNSEG6S
IPC$SMNIDS
IPC$SMNSEMS
```

For more information about these SYS1.PARMLIB statements, see z/OS MVS Initialization and Tuning Reference.
**Tip:** You can issue the operator command to display these values.

### Starting the rpcbind address space

There are two ways to start rpcbind as a z/OS UNIX socket application:

- From the z/OS shell
- As a started task

It cannot be started from TSO.

To start rpcbind from the z/OS shell, the user ID must be an authorized superuser. The authorized superuser ID can issue to start rpcbind. For information about assigning superuser attributes, see z/OS UNIX System Services Planning.

You can also start rpcbind as a started task from the MVS console with the START command, as follows:

```bash
START RPCBIND
```

You can specify the following options when you are starting rpcbind:

- Specify `-d` for rpcbind to send trace information to the daemon facility of syslogd.
  - `-df` sends flow information.
  - `-dl` sends log information of all RPC procedures called.
  - `-dx` sends XDR information.
- The `-i` option enables you to specify the z/OS UNIX file system directory to which the pid file is written. The pid file name is always rpcbind.pid. If `-i` is not specified, the rpcbind process ID is written to `/etc/rpcbind.pid`.

**Restriction:** The directory path name must be an absolute path name. That is, it must begin with the forward slash (`/`) character, as shown in the following example:

```bash
rpcbind -i /tmp
```

- The `-n` option enables you to direct rpcbind to run in a non-swappable environment. A process might need to run as non-swappable to ensure that it is available during periods of high CPU usage. However, a non-swappable process might convert real storage in the system to preferred storage. Because preferred storage cannot be configured offline, allowing rpcbind to run in a non-swappable state can reduce the future ability of your installation to reconfigure storage.

  If you do specify the `-n` option, ensure that the user ID associated with rpcbind has at least READ access to the resource profile BPX.STOR.SWAP in the FACILITY class. The default is to start rpcbind as swappable.

- The `-s` option specifies the number of statistics entries per binding protocol that rpcbind maintains. Valid values are in the range 113 – 500. Statistics that are maintained by the rpcbind server are used to reply to the RPCBPROC_GETSTAT request. For more information about statistics that are maintained by the rpcbind server, see RFC 1833.

**Result:** Rpcbind calculates the number of pages that are needed to store statistics for the value that is specified, and obtains that number of pages of shared memory for statistics. Rpcbind rounds up the number of statistics entries it tracks to fully use the shared memory.

**Tip:** Rpcbind does not start unless it can obtain sufficient shared memory to maintain statistics for the number of entries you specify. You configure the number of pages of shared memory available to z/OS with the IPCSSHMMPAGES parameter in the BPXPRMxx member of SYS1.PARMLIB.

- To display help information, specify the `-?` option.

**Tip:**

- If your system is using the Network File System (NFS) server, for more information about initialization attributes for the z/OS client and Network File System operation, see z/OS Network File System Guide and Reference.
• The rpcbind server uses ENF event code 80 to send signals when rpcbind completes initialization and when rpcbind is stopping. For more information, see Using ENF event code 80 to listen for rpcbind events in z/OS Communications Server: IP Programmer’s Guide and Reference.

Restriction: Portmapper and rpcbind cannot be run at the same time, as they both listen on /etc/services sunrpc port 111.

Steps for configuring the NCS interface

This topic describes how to configure the Network Computing System (NCS).

NCS is the Remote Procedure Call (RPC) implementation of Apollo's Network Computing Architecture (NCA**).

NCS includes:
1. RPC runtime library
2. Location broker
3. Network Interface Definition Language (NIDL) compiler

The RPC runtime library and the location broker provide runtime support. Together these two elements make up the Network Computing Kernel (NCK) which includes all the software necessary to run a distributed application. The NIDL compiler is a tool for developing NCS-based applications.

In order to execute NCS applications in an MVS environment, you must start a local location broker (LLBD). One of the hosts in your IP network must also start the global location broker (GLBD). Both the LLBD and the NRGLBD maintain information about active NCS server applications.

• LLBD server
   The LLBD manages the LLB database which stores information for the NCS-based servers running on this host.

   Your host must run LLBD if you want to support the location broker forwarding function or allow remote access to the LLB database. The LLBD function must be started on the host before any other NCS-based servers are started and before the NRGLBD is started.

   The LLB database is stored in the data set ADM@SRV.LLB@LL.DATABASE, which is not created until an entry is registered with the LLBD. This data set can be administered using the lb@admin tool.

• NRGLBD server
   The NRGLBD manages the NCS global location broker (GLB) database. The GLB helps clients locate servers on a network or internet.

   There are two versions of the GLB daemon: replicated GLBD and NRGLBD. The replicated GLBD is available only on Apollo, SunOS, and Ultrix systems. For other systems, such as IBM, only the NRGLBD is available. The advantage of replicated GLBD over NRGLBD is that the GLBD can be run at the same time on several network hosts, providing greater availability in the event that one of the hosts running GLBD fails or if there is a partial network failure.

   You cannot use the NRGLBD on your system if:
   – The replicated version of GLBD can run on some other host in your network
   – Another host in your network is already running NRGLBD

   The GLB database is stored in a data set ADM@SRV.LLB@LG.DATABASE. This data set is not created until an entry is registered with the NRGLBD.

   The record structure for the LLBD and the NRGLBD databases is identical.

Perform the following steps to configure NCS:
1. Specify AUTOLOG and PORT statements in hlq.PROFILE.TCPIP.
2. Update the NRGLBD cataloged procedure in SEZAINST(NRGLBD).
3. Update the LLBD cataloged procedure in SEZAINST(LLBD).

For more information about NCS, see *Network Computing System Reference Manual*.

**Step 1: Configuring PROFILE.TCPIP for NCS**

If you want LLBD and NRGLBD to start automatically when the TCPIP address space is started, then you should include the names of the members containing the LLBD and NRGLBD cataloged procedures in the AUTOLOG statement in the `hlq.PROFILE.TCPIP` data set.

The LLBD must be running before you start NRGLBD. Therefore, you must put LLBD before NRGLBD in the AUTOLOG statement.

```
AUTOLOG
  LLBD
  NRGLBD
ENDAUTOLOG
```

To ensure that port UDP 135 is reserved for the LLBD server, add the name of the member containing the LLBD cataloged procedure to the PORT statement in the `hlq.PROFILE.TCPIP` data set.

```
PORT
  135 UDP LLBD
```

See the *z/OS Communications Server: IP Configuration Reference* for more information about the AUTOLOG and PORT statements.

**Step 2: Updating the NRGLBD cataloged procedure**

Update the NRGLBD cataloged procedure by copying the sample provided in SEZAINST(NRGLBD) to your system or recognized PROCLIB and modifying it to suit your local conditions. See the NCS topic in *z/OS Communications Server: IP Configuration Reference* for more details.

**Step 3: Updating the LLBD cataloged procedure**

Update the LLBD cataloged procedure by copying the sample provided in SEZAINST(LLBD) to your system or recognized PROCLIB and modifying it to suit your local conditions. See the NCS topic in *z/OS Communications Server: IP Configuration Reference* for more information.
Chapter 26. Mail on z/OS

This topic describes how to configure the Communications Server SMTP (CSSMTP) application and popper.

CSSMTP is the strategic mail program for z/OS Communications Server and should be used for forwarding mail from your NJE network or from local applications that write mail to a JES spool file, using the existing SMTP batch interface to forward the mail to other gateway servers. CSSMTP provides the easiest and simplest solution for this purpose.

The sendmail to CSSMTP bridge is a replacement for the z/OS UNIX sendmail command for sending mail:

• The sendmail bridge processes the sendmail command input options (supported command line switches and configuration statements), reads the mail file, and constructs a CSSMTP compatible file with SMTP commands.
• Basic sendmail commands that use the sendmail bridge should function seamlessly, but more advanced options might require alternate solutions.
• The sendmail bridge requires CSSMTP to be configured and running.

Note: CSSMTP and the sendmail bridge don't provide support for receiving mail for delivery to local TSO/E or z/OS UNIX System Services user mailboxes, or for forwarding mail to other destinations.

Configuring the CSSMTP application

Communications Server Simple Mail Transfer Protocol (CSSMTP) is a mail-forwarding SMTP client application. CSSMTP processes data sets containing mail messages on the spool file and forwards them to a target message transfer agent (MTA) without resolving each recipient. CSSMTP can improve the performance, scalability, and availability of the client function, but it does not act as a listening MTA server. Multiple instances of CSSMTP can run on a single host. Figure 150 on page 1251 shows how CSSMTP fits into a network.

![CSSMTP fits into a network](image)

Figure 150. CSSMTP forwards mail messages from spool to the network

© Copyright IBM Corp. 2000, 2019
CSSMTP implements RFC 2821 and RFC 2822 for interacting with server MTAs, and supports additional RFCs for message size (RFC 1870) and security (RFC 3207). CSSMTP is not a fully capable MTA and functions as an outbound forwarder, sending mail messages from the JES spool data set to the Internet. As the mail messages are read from the spool file, CSSMTP functions like a TCP/IP SMTP client and interacts with one or more configured target servers. When processing mail messages from the spool file, CSSMTP does not resolve mail message recipients, but transfers mail messages to one or more configured, next-hop servers (fully capable MTAs) that might or might not be the final destination.

CSSMTP provides the following capabilities:

- **Checkpoint capabilities**
  
  If you need to restart CSSMTP, it does not have to reprocess the entire spool file, which will reduce duplicate mail that is received by message recipients.

- **Long retry and extended retry capabilities**
  
  - The long retry capability is available for up to 5 days, and is intended to compensate for short-term target server outages.
  
  - The extended retry capability is available for a longer period or for an indefinite period, and is intended to compensate for extended target server outages.

  For more information, see “Customizing the CSSMTP configuration file to try mail again” on page 1257.

- **Multiple security capabilities**
  
  See “Security for CSSMTP” on page 1259.

- **SMF recording of CSSMTP events**
  
  See “Steps for configuring SMF records for CSSMTP (optional)” on page 1263.

As stated in RFC 2821, SMTP clients that transfer all traffic, regardless of the target domain names that are associated with the individual mail messages, or that do not maintain queues for trying mail message transmissions again that initially cannot be completed, might otherwise conform to this specification but are not considered fully capable. CSSMTP does not implement all aspects of RFC 2821.

**Terms and concepts**

The following terms and concepts are used in this information:

- **Backpressure**
  
  CSSMTP stops processing the JES spool file when mail cannot be sent to the target because the connection to a target server is down or unresponsive. CSSMTP resumes processing the JES spool file when a target server connection becomes active.

- **Bad spool file**
  
  A bad spool file is a JES spool file that cannot be processed as the result of security, configuration, syntax, readability, or delivery issues. The action taken by CSSMTP is subject to the setting of the BadSpoolDisp statement. For more information about the BadSpoolDisp statement, see z/OS Communications Server: IP Configuration Reference.

- **Checkpointing**
  
  If checkpointing is enabled using the CHKPOINT DD statement in the CSSMTP started procedure and there are partially processed spool files on the spool when restarting, CSSMTP attempts to send only the mail from these spool files that was not previously sent, which reduces the duplicate mail that is received by recipients. If CSSMTP is started cold using the -f option, any existing checkpoint records are flushed before CSSMTP is restarted. For information about using the CHKPOINT DD statement in the CSSMTP started procedure and about starting CSSMTP with the -f start option, see z/OS Communications Server: IP Configuration Reference.

- **Dead letter**
  
  A dead letter is created and stored for the following reasons:
  
  - An undeliverable mail notification cannot be returned to the originator
  
  - The original mail message was undeliverable, but did not specify an originator
• An error report cannot be delivered to the mail administrators

To ensure that dead letters are stored, configure Store on the DeadLetterAction parameter of the Undeliverable statement. For information about the Undeliverable statement, see z/OS Communications Server: IP Configuration Reference.

For examples of customizing the configuration to handle undeliverable mail, see “Customizing the CSSMTP configuration file to handle undeliverable mail” on page 1258.

ESMTP
Extended Simple Mail Transfer Protocol

Extended retry
If a mail message is not sent to all recipients because the target servers replied with a retry reply code, another attempt to send the message is made after the delay that is defined by the RetryLimit statement. If the long retry limits that are defined by the RetryLimit statement are exceeded, the mail is placed in the extended retry state. The mail is saved in a z/OS UNIX file system directory for extended retry as defined by the ExtendedRetry statement. If the extended retry limit is exceeded, the mail is marked as undeliverable. For more information about mail retry, see “Customizing the CSSMTP configuration file to try mail again” on page 1257. For information about using the RetryLimit statement and the ExtendedRetry statement to configure the retry limits, see z/OS Communications Server: IP Configuration Reference.

Long retry
See the definition for extended retry.

Mail administrator
The mail administrator is a special user ID for mailing systems, to which CSSMTP delivers error reports for problems detected while processing a spool file from the JES spool data set. For information about using the MailAdministrator statement to configure up to four mail administrator addresses, see z/OS Communications Server: IP Configuration Reference.

Message content
The headers and the structured body of a mail message. A separate Multipurpose Internet Mail Extensions (MIME) specification provides the definitions for structured bodies.

MTA
Message transfer agent

SMTP
Simple Mail Transfer Protocol

SMTP command
A command sent from the client to the SMTP server that lets the server know what information is being sent. For example, MAIL FROM: is a command.

SMTP reply
The acknowledgement, positive or negative, sent from an SMTP server. Replies are in the ASCII character set of the target server.

SMTP server
A network application implementing the SMTP protocol that accepts mail messages from SMTP clients.

Target server
A target server is the resolved or configured IP address from a TargetServer statement. The first four target servers are used by CSSMTP. For information about using the TargetServer statement to configure a target server, see z/OS Communications Server: IP Configuration Reference.

Undeliverable mail
Mail messages that cannot be delivered. CSSMTP processes and tries to send all mail messages in the spool file. Sometimes, one or more of these mail messages might be undeliverable. Examples of what causes undeliverable mail include:

• A problem with the mail message itself, such as the message size
• A problem with the recipient record (RCPT TO:), such as an unknown mailbox
• A mail message requires a secure connection and none of the target servers support the STARTTLS SMTP command

• Security problems

• A networking problem, such as being unable to reach a target host that has the capabilities that are needed for the mail message

For examples of customizing the configuration to handle undeliverable mail, see “Customizing the CSSMTP configuration file to handle undeliverable mail” on page 1258.

Undeliverable mail notification
CSSMTP creates an undeliverable mail notification when the ReturnToMailFrom parameter is set to YES on the Undeliverable statement and the mail message cannot be delivered. This notification contains the reply from the target server, describing the reason that the mail message was undeliverable and the text of the original mail message. If the undeliverable mail notification cannot be sent immediately, it is not tried again and is subject to the setting of the DeadLetterAction parameter of the Undeliverable statement.

For examples of customizing the configuration to handle undeliverable mail, see “Customizing the CSSMTP configuration file to handle undeliverable mail” on page 1258.

Setting up CSSMTP
To set up CSSMTP to process and forward your mail, you must take the following actions:

• Configure and start CSSMTP.

  See “Steps for configuring and starting CSSMTP” on page 1254.

• Create mail on the JES spool data set for CSSMTP.

  See “Steps for creating mail on the JES spool data set for CSSMTP” on page 1255.

Steps for configuring and starting CSSMTP
You can use CSSMTP to process and forward your mail. These steps provide the minimum information that you need to configure and start CSSMTP.

Procedure
Perform the following steps to configure and start CSSMTP:

1. Create a new data set member in your procedure library for the CSSMTP JCL.

   A sample job is in SEZAINST(CSSMTP). Because the CSSMTP JCL sample contains a JOB card, you should define the procedure library that you use in the IEFJOBS or IEFPDSI concatenation of the master JCL, or put the new data set member in a subsystem procedure library such as SYS1.PROCLIB.

2. Define explicit authority for all user IDs that you want to be able to start CSSMTP.

   See “Steps for granting authority to start CSSMTP” on page 1259.

3. Customize the CSSMTP configuration file and set up at least one valid target server IP address using the TargetServer statement.

   A sample CSSMTP configuration file is included in member CSSMTPCF in SEZAINST. A target server is defined as the IP address that is resolved from or configured on the TargetServer statement. For information about using the TargetServer statement to configure a target server, see z/OS Communications Server: IP Configuration Reference. For information about other configuration statements used by CSSMTP, see z/OS Communications Server: IP Configuration Reference. For information about handling undeliverable mail, see “Customizing the CSSMTP configuration file to handle undeliverable mail” on page 1258.

   CSSMTP configuration statements are processed during the initialization of CSSMTP or when you issue the MODIFY procname,REFRESH command.

4. Set up the resolver search order.

   Use the default search order unless there are special circumstances that require you to use unique parameters. For example, if the resolver has parameters that are used only when the resolver is called
by CSSMTP, you need to define those unique parameters. Define the unique parameters in a data set that is specified on the SYSTCPD DD statement in the CSSMTP procedure JCL. For more information about resolvers and resolver configuration files, see Chapter 13, “The resolver,” on page 703.

5. Optionally, set up additional security for CSSMTP.
   See “Security for CSSMTP” on page 1259.

   A sample job is in SEZAINST(CSSMTPVL).

7. Set up the timezone using the TZ environment variable.
   If you do not set up the timezone, the timezone is not shown in the Received header line, which is used to indicate that CSSMTP has picked up a mail message. The default time value is used if the DATE header is not specified in the mail message.

8. Start CSSMTP by issuing the following command, where csproc is the CSSMTP procedure member name:

   START csproc

**Results**

You know you are done when initialization is complete and you have successfully connected to the specified target server for processing mail, as indicated by the following messages:

```
EZD1802I csproc INITIALIZATION COMPLETE FOR extWrtName
EZD1821I csproc ABLE TO USE TARGET SERVER ipAddress
```

**Steps for creating mail on the JES spool data set for CSSMTP**

This topic provides the minimum information that you need to create mail that can be processed and forwarded by CSSMTP.

**Before you begin**

You need to know the external writer name of the CSSMTP application that you want to process your mail data set. If the external writer name is not configured for CSSMTP using the ExtWrtName statement, then the default is the job name. For information about configuring the external writer name using the ExtWrtName statement, see z/OS Communications Server: IP Configuration Reference.

For more information about creating mail using CSSMTP commands, see z/OS Communications Server: IP User's Guide and Commands.

**Procedure**

Perform the following steps to create mail on the JES spool data set for CSSMTP:

1. Set up JES so that CSSMTP can create, read, write, and purge data from the JES spool data set.
   See “Steps for initial setup for CSSMTP” on page 1256.

2. Set up the mail to conform to the standardized syntax for text messages that are sent across networks.
   Mail messages have an envelope and contents. Envelopes contain all necessary information to accomplish transmission and delivery of the mail message content. The fields in the envelope are in a standard format.

3. Configure code page support.
   - If multi-byte character support is required, configure the MBCS YES statement.
   - Configure the code page of the input spool files with the TRANSLATE statement. The spool file must be written by using a code page that is supported by z/OS Unicode Services. The default TRANSLATE code page is IBM-1047. If MBCS YES is configured, the TRANSLATE code page must be a multi-byte character set code page.
   - Configure the code page used by the mail servers with the Charset parameter defined on the TargetServer statements. The default Charset code page is ISO8859-1.
- If MBCS YES is configured, configure the code page used by the mail servers with the MBCharset parameter defined on the TargetServer statements. The MBCharset code page must be a multi-byte character set code page.

The spool file that contains the mail commands and body is recognized and translated by the Language Environment iconv function to the following code pages:

- The mail commands are translated from the TRANSLATE code page to EBCDIC (IBM-1047) for inspection by CSSMTP and then from IBM-1047 to the Charset code page before sending to the target server.
- The mail headers are translated from the TRANSLATE code page to EBCDIC (IBM-1047) for inspection by CSSMTP and then from the TRANSLATE code page to the Charset or MBCharset code page before sending to the target server.
- The mail body is translated from the TRANSLATE code page to the Charset or MBCharset code page before sending to the target server.

For information about Unicode Services, see z/OS Unicode Services User's Guide and Reference. For information about configuring the code page by using the MBCS statement, the Translate statement, and the Charset and MBCharset parameters on the TargetServer statement, see z/OS Communications Server: IP Configuration Reference.

4. Set up the mail in one of the following formats:

- A flat file generated using the sendmail bridge command that writes to the SYSOUT data set

  For information about using the sendmail bridge command, see Sendmail to CSSMTP bridge in z/OS Communications Server: IP User's Guide and Commands.

- A flat file generated using the IEBGENER utility or batch jobs that write to the SYSOUT data set

  For information about using the IEBGENER utility to copy a mail file to a JES SYSOUT data set, see z/OS Communications Server: IP User's Guide and Commands.

- Netdata generated from SMTPNOTE or from TSO xmit

  For information about using the SMTPNOTE command to compose a single mail message to one or more recipients and about using the TSO TRANSMIT (XMIT) command to send a mail file, see z/OS Communications Server: IP User's Guide and Commands.

You must copy and customize the SMTPNOTE CLIST on every system where users can send mail with the SMTPNOTE command. For more information, see “Steps for customizing the SMTPNOTE CLIST (optional)” on page 1257.

Results
You know you are done when mail is on the JES spool data set ready to be processed by CSSMTP.

Steps for initial setup for CSSMTP
Set up JES so that CSSMTP can create, read, write, and purge data from the JES spool data set.

Procedure
Perform the following steps to set up JES:

1. Set up JES2 or JES3 initialization parameters so that CSSMTP can interface with JES utilities to create, read, write, and purge data from the JES spool data set.

   For information about JES2 initialization, see z/OS JES2 Initialization and Tuning Guide. For information about JES3 initialization, see z/OS JES3 Initialization and Tuning Guide. For information about JES RACF authorization, see z/OS Security Server RACF Security Administrator's Guide.

2. Verify that JES exit programs do not interfere with the function of CSSMTP.

   For JES2 exit and exit routine association, see z/OS JES2 Initialization and Tuning Reference. For JES3, if you are using the IATUX18 exit, see z/OS JES3 Customization.

3. Set up security authorization for the CSSMTP started task name in your definitions of authorized users.
If you are using RACF for security, see z/OS Security Server RACF Security Administrator’s Guide for information about RACF controls for the spool file.

4. Set up CSSMTP for warm starts by configuring the CHKPNT DD statement.

Checkpointing enables CSSMTP to recognize partially processed spool files, so that CSSMTP does not reprocess the entire spool file when restarting. This reduces the duplicate mail messages that are received by mail message recipients. Warm starts work only when restarting CSSMTP with the same job name and external writer name. If CSSMTP is started cold using the -f option, any existing checkpoint records are flushed before CSSMTP is restarted. For information about using the CHKPNT DD statement in the CSSMTP started procedure and about starting CSSMTP, see z/OS Communications Server: IP Configuration Reference.

Steps for customizing the SMTPNOTE CLIST (optional)

Perform these steps for every system from which mail can be sent using the SMTPNOTE command.

Before you begin

If the ExtWrtName statement is specified in the CSSMTP configuration file, you should change the configured SMTPJOB value in the SMTPNOTE CLIST to match the ExtWrtName name of CSSMTP. If the ExtWrtName statement is not specified, you should customize the SMTPJOB name to match the CSSMTP job name. The SMTPJOB name must not be defined as a node name to JES and cannot begin with the characters R, RM, or RMT, because SMTPNOTE uses TSO XMIT to transmit the mail to CSSMTP.

Procedure

Perform the following steps to customize the SMTPNOTE CLIST:

1. Copy SEZAINST(SMTPNOTE) into the system CLIST data set.
2. Customize the variables in the SMTPNOTE CLIST, including the SMTPJOB variable so that it uses the CSSMTP job name. DOMAIN should also be set when using CSSMTP. For more information, see Step 3: Customize the SMTPNOTE CLIST and modify parmlib data sets.

Customizing the CSSMTP configuration file to try mail again

When mail servers reply to commands that resources are temporarily unavailable, CSSMTP can try sending mail messages again. CSSMTP implements the following two types of retry:

- Long retry, defined by the RetryLimit statement

  When you configure long retry, mail messages are saved in CSSMTP memory while they await retry. The originating spool file is also held by CSSMTP until every mail message is delivered or until an undeliverable notice is sent. Because the originating spool file is held during retry processing, you should configure the RetryLimit statement to a time span that is shorter than the time span that you configure for extended retry. For example, the time span on the RetryLimit statement might be several hours.

- Extended retry, defined by the ExtendedRetry statement

  When you configure extended retry, mail messages that were undeliverable at the end of the long retry period are tried again for an extended period after the originating spool file is released. During the extended retry period, mail messages are saved in a z/OS UNIX file system directory. Because the originating spool file is released during extended retry processing, you can configure the ExtendedRetry statement to a longer time span than the time span that you configure for long retry. For example, the time span on the ExtendedRetry statement might be several days.

You can use these statements individually or at the same time to provide the best system environment for mail processing.

For example, the following statements set long retry to 1 hour and extended retry to 3 days:

```
RetryLimit
{
  Count 6
  Interval 10
}
```
Tip: Because CSSMTP is a mail forwarder, the likelihood of receiving retry reply codes from a message transfer agent (MTA) is low. You are most likely to receive these errors when the MTA is also the home mail server for the mail recipients and the MTA reports errors that are related to the mailboxes of the recipients on the MTA. One possible error is that the mailbox is full.

Customizing the CSSMTP configuration file to handle undeliverable mail

CSSMTP provides configuration options to indicate how it handles undeliverable mail messages. You can configure CSSMTP to send individual undeliverable mail notifications or not to send them. You can also configure CSSMTP to create a report describing errors that were found while processing mail messages; this report can be created on the spool or sent to the configured mail administrators.

The following examples describe the configuration options for handling undeliverable mail. For more information about the BadSpoolDisp statement, the Undeliverable statement, the MailAdministrator statement, and the Report statement, see z/OS Communications Server: IP Configuration Reference.

• Example 1 — Configuring CSSMTP to not return an undeliverable mail notification to the originator and to hold the original spool file on the JES spool data set:

```
BadSpoolDisp       Hold
Report             Admin
MailAdministrator  myuserId@ibm.us.com
Undeliverable     {
    ReturnToMailFrom No
}
```

To configure the application to not send an undeliverable mail notification to the originator, you need to set the ReturnToMailFrom value to No. This example might be useful if the mail messages do not specify an originator, or if the spool file is for sending bulk mail that does not typically require a reply to the originator. This example has optionally configured that a report be sent to the specified mail administrator.

Tips:

– The mail administrator can use the received report to determine which mail messages were undeliverable in the original spool file.
– When the examination of this JES spool file is complete, the mail administrator should delete the JES spool file, which is now in a hold state.

Results:

– CSSMTP tries to send all mail messages, and if any of the mail is undeliverable, CSSMTP does not create and send an undeliverable mail notification.
– Because the BadSpoolDisp statement is set to Hold, CSSMTP does not delete the JES spool file.

• Example 2 — Configure CSSMTP to send an undeliverable mail notification to the originator, and to hold the original spool file on the JES spool data set if necessary:

```
BadSpoolDisp       Hold
Report             None
Undeliverable     {
    ReturnToMailFrom Yes
    DeadLetterAction  Store
    DeadLetterDirectory /var/cssmtp/myDir/
}
```

To configure the application to send an undeliverable mail notification to the originator, you need to set the ReturnToMailFrom value to Yes. This example might be useful if the mail messages do specify an originator.
This example is useful if the originator of the mail messages needs to be informed that the messages cannot be delivered. If you determine that it is not necessary to inform the originator of failed deliveries, set the ReturnToMailFrom value to No. No report is created in this example.

**Tip:** When spool files contain many mail messages, this configuration should be used with caution because a failure can cause many individual undeliverable mail notifications to be maintained in storage while trying to return them to the originator.

**Results:**
- CSSMTP builds an undeliverable mail notification and attempts to notify the originator of the mail message failure.
- Because the ReturnToMailFrom value is Yes, if the original spool file contains no errors other than undeliverable mail errors, CSSMTP always deletes the spool file even when the BadSpoolDisp value is set to Hold.
- If the original spool file contains both undeliverable mail errors and syntax errors, CSSMTP holds the spool file because the BadSpoolDisp value is set to Hold.
- If the undeliverable mail notification cannot be returned to the originator of the mail message, then this undeliverable mail notification becomes a dead letter. The action taken by CSSMTP is based on the value configured on the DeadLetterAction parameter. In this example, because the DeadLetterAction value is set to Store, CSSMTP stores the dead letters in the /var/cssmtp/myDir directory:

```
/var/cssmtp/myDir/TESTMAIL.SYS00006.Sep302008.160454.541437.1U
/var/cssmtp/myDir/TESTMAIL.SYS00006.Sep302008.160454.541999.1U
```
- Because None is specified on the Report statement, the log must be inspected for messages about any problems found in the JES spool file.

**Steps for granting authority to start CSSMTP**

Define explicit authority for all user IDs that you want to be able to start CSSMTP.

**Procedure**

Perform the following steps to grant authority to a user ID to start CSSMTP:

1. Ensure that the OPERCMDS class is active and RACTIONed, and that RACLST processing is enabled.
2. Define the OPERCMDS class profile using a security product like RACF.
3. Grant CSSMTP access to the OPERCMDS class and then refresh the OPERCMDS class.

**Results**

Depending on how you start CSSMTP, some RACF profiles that restrict who can issue the START, CANCEL, MODIFY, or STOP operator commands are as follows:

```
MVS.START.STC.CSSMTP.*
MVS.START.STC.CSSMTP
MVS.CANCEL.STC.CSSMTP.*
MVS.CANCEL.STC.CSSMTP
MVS.MODIFY.STC.CSSMTP.*
MVS.MODIFY.STC.CSSMTP
MVS.STOP.STC.CSSMTP.*
MVS.STOP.STC.CSSMTP
```

For more information about protecting operator commands, see z/OS MVS Planning: Operations.

**Security for CSSMTP**

Consider the following additional security measures for CSSMTP:
For spool files from NJE nodes, the user ID associated with the spool file must be defined by SAF. For more information about the protection of SYSOUT data sets, see the following topics:

- Protecting Data Sets on Spools in z/OS Security Server RACF Security Administrator’s Guide
- Authorizing SYSOUT in z/OS Security Server RACF Security Administrator’s Guide
- Authorizing SYSOUT in z/OS JES2 Initialization and Tuning Guide
- Understanding default userids in z/OS JES2 Initialization and Tuning Guide
- Using RACF to Provide Security in z/OS JES3 Initialization and Tuning Guide
- Understanding Default User IDs in z/OS JES3 Initialization and Tuning Guide

If your installation protects access to the JESSPOOL class of resources, provide ALTER access to the CSSMTP user ID so that it can read and delete spool files. An example JESSPOOL definition follows:

```
//CSSMTP   EXEC PGM=IKJEFT01
//SYSTSprt DD SYSOUT=*  
//* The PERMIT for CLASS(JESSPOOL) is needed only if it has already *
//* been activated. 
//SYSTSIN DD *  
SETROPTS CLASSACT(STARTED)  
SETROPTS RACLIST(STARTED)  
SETROPTS GENERIC(STARTED)  
ADDUSER CSSMTP DFLTGRP(OMVSGRP) OMVS(UID(nn) HOME('/'))           -  
NOPASSWORD NAME('Simple Mail Transfer') OWNER(OMVSGRP)  
RDEFINE STARTED OWNER(SYS1) CSSMTP.* STDATA(USER(CSSMTP))  
RDEFINE JESSPOOL localnodeid.** UACC(READ)  
PERMIT localnodeid.** -  
CLASS(JESSPOOL) ID(CSSMTP) ACCESS(ALTER)  
SETROPTS GENERIC(JESSPOOL) REFRESH  
SETROPTS RACLIST(STARTED) REFRESH  
SETROPTS GENERIC(STARTED) REFRESH
```

When CSSMTP is defined with a nonzero UID value, Delete Operator Message (DOM) messages are prefixed with message BPXM023I. To remove the prefix, you must authorize the CSSMTP procedure user ID to use the UNIX System Services console service. You can authorize CSSMTP to use the console service by entering the following commands:

```
RDEFINE FACILITY BPX.CONSOLE UACC(NONE)  
PERMIT BPX.CONSOLE -  
CLASS(FACILITY) ID(CSSMTP) ACCESS(READ)  
SETROPTS RACLIST(FACILITY) REFRESH
```

You can control whether CSSMTP reads and processes the spool files created by specific users by creating one or more resource profiles in the SERVAUTH class.

The format of the SERVAUTH profile name is EZB.CSSMTP.sysname.writername.originJESnode, where `sysname` is the system name defined in the sysplex, `writername` is the CSSMTP configured external writer name, and `originJESnode` is the JES node that originated the spool file. If this profile is created with UACC(NONE), then only user IDs permitted to the resource are able to have spool files processed by CSSMTP.

For examples of the resource profile definitions, see the EZARACF sample in data set SEZAINST. For information about configuring the external writer name using the ExtWrtName statement, see z/OS Communications Server: IP Configuration Reference.

**Tips:**

- You can specify a wildcard on segments of the profile name, as shown in the following example:

```
SETR GENERIC(SERVAUTH) GENCMDS(SERVAUTH)  
SETR CLASSACT(SERVAUTH)  
RDEFINE SERVAUTH EZB.CSSMTP.sysname.writername.originJESnode -  
UACC(NONE)  
PERMIT EZB.CSSMTP.sysname.writername.originJESnode -  
CLASS(SERVAUTH) ID(userid) ACCESS(READ)  
PERMIT EZB.CSSMTP.sysname.writername.* -
```
You can define multiple profiles. For example, if this CSSMTP instance processes spool files from local jobs and from remote systems, you can define a profile for the local system and for each JES node that originates spool files. The spool file is matched to the most specific RACF profile, and then the user ID associated with the spool file is validated against that profile.

Result: If the profile is active with UACC(NONE), then when the spool file is received on the JES spool data set, CSSMTP checks to determine whether a profile is defined for the originating node or for any originating node (*), and then checks whether the user ID associated with the job that created the spool file is permitted to the profile:

- If the user ID is permitted, the spool file is processed by CSSMTP.
- If the user ID is not permitted, the spool file is considered to be a bad spool file and is subject to the action specified by the BadSpoolDisp statement. For more information about the BadSpoolDisp statement, see z/OS Communications Server: IP Configuration Reference.

If the profile is not defined, then the spool file is processed as if the user ID is permitted.

You can write a CSSMTP user exit or use the existing SMTPD user exit to inspect mail before it is sent to a target server.

For example, you can create an exit to check the MAIL FROM: string on outbound mail. The mail originator, recipients, and other information can be inspected by the exit, and the entire JES job or a single mail message can be discarded.

You can control the user exit that is used with the UserExit statement:

- If you want to use a user exit that you have written for CSSMTP, then specify Version3 on the UserExit statement. You need to use this version if you want to use both RFC 821 and RFC 2821 commands to read and process from the JES spool data set. For more information about the CSSMTP exit, see z/OS Communications Server: IP Configuration Reference.
- If you want to continue using your SMTPD user exit and use only RFC821 commands, then specify Version2 on the UserExit statement.

For more information about the UserExit statement, see z/OS Communications Server: IP Configuration Reference.

You can enable the SMTP server and client to use Transport Layer Security (TLS) to provide private, authenticated communication over the Internet using RFC 3207, SMTP Service Extension for Secure SMTP over Transport Layer Security. For more information, see “Steps for using Transport Layer Security for CSSMTP” on page 1261.

Steps for using Transport Layer Security for CSSMTP

You can enable the SMTP server and client to use Transport Layer Security (TLS) to provide private, authenticated communication over the Internet.

Procedure

Perform the following steps to use Transport Layer Security (TLS) for CSSMTP:

1. Set up secure mail using the YES option on the Secure parameter of the TargetServer statement, the STARTTLS command in the JES batch job, or both.

Table 72 on page 1261 shows whether TLS is required between CSSMTP and a target server based on various JES batch job and CSSMTP configuration combinations.
If secure communication is required according to Table 72 on page 1261 and no available target servers support TLS (as indicated by server capabilities in response to the EHLO command), the mail message fails and is not delivered.

For information about the TargetServer statement, see z/OS Communications Server: IP Configuration Reference. For information about the STARTTLS command, see z/OS Communications Server: IP User's Guide and Commands.

2. See the following simple example to get started with TLS.

For more information about TLS, see Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1093.

In this example, assume the following characteristics:

- The mail contains sensitive data, and you want CSSMTP to communicate with only TLS protocols.
- CSSMTP is using port 25 to communicate with a target server on another platform.
- There is only one TCP/IP stack over which mail is delivered, referred to as the client stack.

To set up TLS for this sample environment, take the following actions:

a. Create the key ring.

The client key ring needs the root certification used to sign the server certificates. For a TLS/SSL primer and some step-by-step examples, see Appendix B, “TLS/SSL security,” on page 1299. For more information about managing key rings and certificates with RACF and the RACDCERT command, see z/OS Security Server RACF Security Administrator’s Guide. For more information about managing key rings and certificates with gskkyman, see z/OS Cryptographic Services System SSL Programming.

b. Configure CSSMTP to require secure communication. Configure the TargetServer statement with the Secure parameter set to YES, which specifies that TLS protocols are always required. For information about the TargetServer statement, see z/OS Communications Server: IP Configuration Reference.

c. Configure the client system to use TLS with AT-TLS policies as follows:

1) Specify TTLS on the TCPCONFIG statement in the TCP/IP profile for the client stack. For information about the TCPCONFIG statement, see z/OS Communications Server: IP Configuration Reference.

2) Block the ability of applications to open a socket before AT-TLS policy is loaded into the TCP/IP stack by setting up EZB.INITSTACK.sysname.tcpname for the client stack.

3) Create a main Policy Agent configuration file containing a TcpImage statement for the client stack, and create a TcpImage policy file for the client stack. For more information about AT-TLS policy statements, see z/OS Communications Server: IP Configuration Reference.

4) Add a TTLSCfg statement to each TcpImage policy file to identify the TTLSCfg policy file location:

<table>
<thead>
<tr>
<th>TTLSCfg</th>
<th>clientPath</th>
</tr>
</thead>
<tbody>
<tr>
<td>TTLSRule</td>
<td>CSSMTPRule</td>
</tr>
</tbody>
</table>

5) Add the AT-TLS policy statements to the clientPath file:

<table>
<thead>
<tr>
<th>TTLSRule</th>
<th>CSSMTPRule</th>
</tr>
</thead>
<tbody>
<tr>
<td>RemotePortRange</td>
<td>25</td>
</tr>
</tbody>
</table>
Tip: You can use the IBM Configuration Assistant for z/OS Communications Server to generate the AT-TLS Policy Agent files. For information about the IBM Configuration Assistant for z/OS Communications Server, see “Option 1: Use the IBM Configuration Assistant for z/OS Communications Server” on page 1094.

3. If the server requires an EHLO command to be sent after a successful TLS negotiation, configure TLSEhlo Yes on the Options statement in the CSSMTP configuration. For more information, see Options statement in z/OS Communications Server: IP Configuration Reference.

Results
You know you are done when CSSMTP can successfully deliver mail to a target server using secure connections. If SECURE YES is configured and CSSMTP is able to successfully negotiate and establish a TLS session, the following message is displayed:

```
EZD1821I csproc ABLE TO USE TARGET SERVER ipAddress
```

Restriction: To use the STARTTLS command with a target server, the target server must have a certificate that can be validated by the AT-TLS component of z/OS Communications Server as configured by Policy Agent. This certificate can be a self-signed certificate or a certificate that can be validated by a known certificate authority. If the certificate of the server cannot be validated, secure communication with the server fails and mail that requires security cannot be delivered to that server.

Steps for configuring SMF records for CSSMTP (optional)
You can use SMF to record CSSMTP events.

Before you begin
CSSMTP can write System Management Facilities (SMF) records for the following cases:

- When the configuration has been initialized or modified by a MODIFY REFRESH command, a MODIFY LOG,LEVEL command, or a MODIFY USEREXIT command. A CSSMTP application configuration record (CONFIG subtype 48) is written.
- At the end of a connection with a target server, a CSSMTP application connection record (CONNECT subtype 49) is written.
- At the end of the processing for each mail message, a CSSMTP application mail message record (MAIL subtype 50) is written.
- At the end of the processing of a spool file when all the mail messages have been completed, a CSSMTP application spool file record (SPOOL subtype 51) is written.
- When statistical information about the CSSMTP processing at the SMF intervals is required, a CSSMTP application statistical record (STATS subtype 52) is written.
Procedure

Perform the following steps to write SMF records to both the MVS SMF data sets and the real-time SMF NMI. Writing SMF records to the MVS SMF data sets and writing SMF records to the real-time SMF NMI are two independent functions and are controlled by different configuration parameters.

1. Add a SMF119 statement to the CSSMTP configuration file.
   
   This configuration parameter controls which SMF record types are written to the MVS SMF data sets. For example:

   ```
   SMF119
   {
   CONFIG YES
   SPOOL YES
   MAIL NO
   CONNECT YES
   STATS YES
   }
   ```

   In this example, the CONFIG, SPOOL, CONNECT and STATS records will be written to MVS SMF data sets and not the MAIL record.

2. Restart the CSSMTP task or issue a MODIFY REFRESH command to dynamically update CSSMTP with the new SMF119 statement values.

3. Update the TCP/IP profile NETMONITOR statement to forward all of the CSSMTP SMF records that are associated with the CONFIG, SPOOL, CONNECT, and STATS types to an application using the real-time SMF NMI, SYSTCPSM.
   
   These record types are both connection oriented and non-connection oriented (see “5” on page 1264). For more information about SYSTCPSM, see z/OS Communications Server: IP Programmer’s Guide and Reference.

   ```
   NETMONITOR SMFSERVICE CSSMTP
   ```

   For the descriptions of the SMF records see z/OS Communications Server: IP Programmer's Guide and Reference.

4. Update the TCPIP profile NETMONITOR statement to forward all the CSSMTP SMF records associated with the MAIL type to an application using the real-time SMF NMI, SYSTCPSM.

   ```
   NETMONITOR SMFSERVICE CSMail
   ```

   For more information about SYSTCPSM, see z/OS Communications Server: IP Programmer's Guide and Reference.

5. Special considerations for CSSMTP application and NETMONITOR in a CINET environment:

   • The CSSMTP application can be started with the -p parameter to set stack affinity. All the SMF records are written to the real time SMF NMI associated with the stack whose name was specified on the -p parameter. This forces connection oriented SMF records (CONNECT) and non-connection oriented SMF records (CONFIG, SPOOL, MAIL and STATS) to go to the same stack. The CSSMTP and CSMAIL NETMONITOR parameters should be specified in the profile data sets of the stack name to match the name specified on the -p parameter.

   • If the CSSMTP application is started without the -p parameter and multiple stacks are active, then a network management application can not determine the stack that records will be written to. The CSSMTP and CSMAIL NETMONITOR parameters should be specified in the profile data sets of all stacks, so that network management applications can obtain all the records. The network management application will not get redundant records. In this case CSSMTP writes the records to the first stack with an active SMFService application and with the appropriate SMFSERVICE CSMAIL or CSSMTP parameter set.

Monitoring CSSMTP

You can use the following MODIFY commands to monitor CSSMTP:

- MODIFY DISPLAY,Config
Displays the current configuration values.

- MODIFY DISPLAY,IPList
  Displays the current set of target servers to which mail can be sent that are configured or resolved from the TargetServer statement.

- MODIFY DISPLAY,SPoolstatus
  Helps you determine how mail is being processed off the JES spool file.

- MODIFY DISPLAY,TARgets
  Helps you monitor the mail that is being sent to target servers to determine whether mail is being delivered, is being placed in undeliverable states, or is being tried again through long retry queues. This command also helps you determine the list of target servers, their attributes, and the number of mail messages that a target server is accepting.

For information about the MODIFY command for CSSMTP, see z/OS Communications Server: IP System Administrator’s Commands.

sendmail to CSSMTP bridge

The sendmail to CSSMTP bridge (sendmail bridge) allows the user to send emails by using the facilities of z/OS UNIX. The sendmail bridge command parses input command switches, reads the mail message from the UNIX System Services file, and processes the mail message. The input mail message is updated by adding SMTP commands and SMTP headers, if no headers are specified in the input mail message. The updated mail message is transmitted to the JES spool data set that the Communications Server SMTP (CSSMTP) application can process. CSSMTP must be configured and running.

Restriction: The sendmail bridge is only a mail client function.

This topic provides information about how to configure the sendmail bridge.

For more configuration information, see Sendmail to CSSMTP bridge in z/OS Communications Server: IP Configuration Reference and for sendmail bridge command information, see z/OS Communications Server: IP User’s Guide and Commands.
Setting up the sendmail bridge

To set up the sendmail bridge to process and forward your mail, you must take the following actions:

1. Create and customize the configuration file.
   
   See “Steps for creating and customizing the configuration file” on page 1266.

2. Configure and start CSSMTP.
   
   • Issue `cssmtp.proc,display,config` to check if CSSMTP is running
   • If you have not configured and started CSSMTP, see Configuring the CSSMTP application.

3. Consider security for the sendmail bridge.
   
   See “Security considerations for the sendmail bridge” on page 1267.

Steps for creating and customizing the configuration file

You can take the following actions to create and customize the sendmail bridge configuration file:

• Copy the sample file ezatmail.cf from /usr/lpp/tcpip/samples/ to /etc/mail/ezatmail.cf.

  Guideline: If you used z/OS sendmail in previous releases, you can use your existing configuration files with the sendmail bridge: /etc/mail/submit.cf or /etc/mail/sendmail.cf. However, because many statements in those 2 files are not supported for the sendmail bridge, it is suggested that you use ezatmail.cf instead.

  You can use the sendmail bridge command line switch -C to define the configuration file. For the search order of the sendmail bridge configuration file, see z/OS Communications Server: IP Configuration Reference.

• Customize the configuration file:
  
  – If you plan to use an alias name for your mail recipients, you might need to provide an O statement with options AliasFile and MaxAliasRecursion.
− If you plan to limit the number of recipients in one mail message, you might need to provide an O statement with option MaxRecipientsPerMessage.

− If you plan to use a different CSSMTP external writer name from the default name "CSSMTP", you can configure a W statement with the CSSMTP external writer name that matches the name of your CSSMTP application. You can also use the environment variable EZATMAIL_CSSMTP_EXTWRTNAME to define your CSSMTP external writer name. For the search order of the sendmail bridge CSSMTP external writer name, see z/OS Communications Server: IP Configuration Reference.

− You can customize options for the sendmail bridge command. For additional information, see z/OS Communications Server: IP User's Guide and Commands.

Security considerations for the sendmail bridge

• With the sendmail bridge command, the updated input mail message is transmitted to the JES spool data set that the Communications Server SMTP (CSSMTP) application processes. For more information about the protection of SYSOUT data sets, see Security for CSSMTP. You can request Transport Layer Security (TLS) for messages sent by the sendmail bridge command through the configuration statement D{tls_version}. If D{tls_version} is specified, a STARTTLS SMTP command is added. When CSSMTP processes the JES spool data set, CSSMTP ensures a secured connection between CSSMTP and its target server is used to forward the mail message. The value that is defined by D{tls_version} is ignored. The secured connection is setup between CSSMTP and the target mail server based on configured AT-TLS policy.

• It is not required that D{tls_version} is set in the configuration file to ensure a secured connection is used. The user can ensure that a secured connection is used between CSSMTP and its target server by setting the Secure parameter to Yes on the CSSMTP TargetServer configuration statement. See “Steps for using Transport Layer Security for CSSMTP” on page 1261.

• If you plan to invoke the sendmail bridge command by submitting a batch job that uses BPXBATCH, the sendmail bridge assumes user IDs are used when running the command, and these user IDs must be defined to execute sendmail correctly. The commands to define the sendmail user IDs are defined in SEZAINST(EZARACF). The commands are:

```
RDEFINE STARTED SENDMAIL.* STDATA(USER(SENDMAIL))
SETROPTS RACLIST(STARTED) REFRESH
SETROPTS GENERIC(STARTED) REFRESH
```

Configuring popper

POP3 uses port 110. You can define additional ports if there is a need for additional command-line options for popper. For information on the options that might be suitable for your site, see the z/OS Communications Server: IP User’s Guide and Commands.

z/OS UNIX popper will most likely be used by those whose local mailer requires a POP3 server. Typically their administrator will provide them with the address or name of the z/OS running the POP3 server, with instructions on where this information should be used.

The authentication method used in this implementation of popper is user ID and password.

The popper implementation can be divided into four steps:

• Update the /etc/services file.
• Update the /etc/inetd.conf file.
• Create the directory for the temporary maildrop file.
• Start inetd.
Update the `/etc/services` file

You need a port for the POP3 server defined in `/etc/services`. Add the following line to your `/etc/services` file. Note that the well-known port 110 is being used in this example:

```
    pop3                110/tcp popper
```

Update the `/etc/inetd.conf` file

Because popper is invoked by INETD, add the following information to your `/etc/inetd.conf` file, where `-d` indicates to run popper in debugging mode:

```
    pop3       stream tcp nowait bpxroot /usr/sbin/popper popper -d
```

The debugging option is used to confirm correct installation, as shown in “Correct connection” on page 1268.

Create the directory for the temporary maildrop file

When popper is invoked through a Mail User Agent (MUA) client request, such as GET NEW MESSAGES, popper starts to read the user’s mail file system (`/usr/mail/username`) where the data has been stored, and puts this data (if there are messages) in a temporary maildrop file `/usr/mail/popper/username.pop`. The contents of this file are transmitted to the remote client using the existing POP3 TCP connection.

Because the directory does not exist, create it as follows:

```
    /usr/mail/popper/
    chmod 777 /usr/mail/popper
```

The popper uses this directory to create and fill the maildrop file. If this directory is not specified or if permissions are incorrect, you will get an error message similar to the following message:

```
    EZZ7605I: Unable to open temporary maildrop '/usr/mail/popper/username.pop'
```

Also, inside the POP3 session, you will get an error message similar to the following message:

```
    -ERR System error, can’t open temporary file, do you own it?
```

Restrictions:

- If the user maildrop file is a symbolic link, it must have an owning UID or GID that matches the EUID or EGID that is assigned to the popper.
- If the user maildrop file is a hard link or the target of a hard link, users that are outside the owner or group of the directory in which the user maildrop file is stored cannot have write access to the directory.

Start inetd

After updating the inetd.conf file, start INETD. For more information on inetd, see Appendix A, “Setting up the InetD configuration file,” on page 1297. Also see z/OS Communications Server: IP Configuration Reference.

Correct connection

The following example shows a working connection to the popper server:

```
    Debugging turned on
    (v2.3) Servicing request from "hostname.domainname" at xxx.xxx.xxx.xxx
    +OK QPOP (version 2.3) at hostname.domainname starting.
    Sending line "+OK QPOP (version 2.3) at hostname.domainname starting."
    Received:"USER username"
    +OK Password required for username.
    Sending line "+OK Password required for username."
    Received:"pass xxxxxxxx"
```
Creating temporary maildrop `/usr/mail/popper/.username.pop'
uid = 4029, gid = 1
Checking for old `.username.pop' file
Old `.username.pop' file not found, errno (0)
Msg 1 being added to list

**Popper command - administering received mail**

If the receiver MUA does not have direct access to the mail spool file, use Popper to access the mail spool on the local host. z/OS Popper is used when a POP3 server is needed.

**Syntax**

```
popper  - b  <directory name>  
      - d  
      - n  <message count>  
      - s  
      - t  <file name>  
      - T  <timeout>  
      - u  
```

**Parameters**

The following command-line options can be used when you are invoking Popper.
-b <directory name>
   Specifies the name of the directory in which bulletins are found. If not specified, /usr/mail/bulletins is used as the default.

Restrictions:
   • If the bulletins file is a symbolic link, it must have an owning UID or GID that matches the EUID or EGID that is assigned to Popper.
   • If the bulletins file is a hard link or the target of a hard link, users that are outside the owner or group of the directory in which the bulletins file is stored cannot have write access to the directory.

-d
   Requests more debugging messages be turned on.

-n <message count>
   Specifies the number of old bulletins to be delivered to new users. If not specified, no bulletins are delivered.

-s
   Requests statistics logging be turned on.

-t <file name>
   Specifies a trace file for all message logging. If not specified, messages are logged via the syslog facility.

-T <timeout>
   Specifies the time, in seconds, before an idle POP3 connection is terminated. RFC 1939 specifies a minimum timeout of 600 seconds, but in practice such a long timeout does not work well. (When a connection gets aborted, the user is locked out of their mailbox for the timeout period.) If not specified, 120 seconds is used as the default timeout period.

-u
   Requests that the user mailbox be updated on abort. RFC 1939 specifies that mailboxes should not be updated (that is, no messages should be deleted) if a connection is aborted abnormally. This option forces an update to occur despite the aborted connection. If not specified, no update occurs on aborted connections.
TIMED is a daemon that is used to provide the time in response to UDP requests. TIMED gives the time in seconds since midnight January 1, 1900. You can start TIMED from the z/OS shell or as a started procedure. TCP/IP must be started prior to starting TIMED.

**Note:** TIMED is different from the TIME daemon available as an internal daemon of INETD. INETD cannot be used to start and perform as a listener for TIMED.

### Starting TIMED from the z/OS shell

TIMED is installed in the `/usr/lpp/tcpip/sbin/` directory.

To start the TIMED server from the command line, issue the `timed` command.

`timed [-l] [-p port]`

The following parameters are used for the `timed` command:

- `-l`
  - Logs all the incoming requests and responses to the system log. Logged information includes the IP address of the requestor.

- `-p port`
  - The TIMED server usually receives requests on well-known port 37. TIMED uses UDP only. You can specify the port in which requests are to be received.

### Starting TIMED as a procedure

The following sample shows how to start TIMED as a procedure.

```plaintext
//TIMED    PROC

Chapter 28. SNTP daemon

The SNTP daemon (SNTPD) is a TCP/IP daemon that is used to synchronize time between a client and a server. Simple Network Time Protocol (SNTP) is a protocol for synchronizing clocks across a WAN or LAN through a specific formatted message. An External Time Reference (ETR), named stratum 0, is chosen as the highest timer reference used for synchronization. A stratum 1 server is attached to and receives the time from the stratum 0 timer. For example, the z/OS sysplex timer could be a stratum 0 timer, and z/OS Communications Server would be a stratum 1 server. A client attached to the stratum 1 server can also be a stratum 2 server, receiving the time from the stratum 1 server, and so on. SNTP uses UDP packets for data transfer with the well-known port number 123. RFC 2030 (Mills 1996) describes SNTP. You can start SNTPD from the z/OS shell or as a started procedure. TCP/IP must be started prior to starting SNTPD.

Restrictions:

• The SNTP server only processes requests with a Mode value of 1 through 4. The SNTP server discards requests whose Mode value is 0, or is greater than 4.

• As per RFC 2030, the SNTP server discards requests whose length is less than the minimum required length of 48 bytes.

SNTPD is an SNTP server. If the server is configured for unicast mode only (that is, neither the multicast mode or the broadcast mode start parameters are specified), then the server just waits for requests from clients and then responds. If the server is also configured for multicast or broadcast mode, it sends unsolicited messages at the intervals that are specified on the multicast mode or the broadcast mode start parameters.

The /etc/sntpd.pid is a temporary SNTP daemon pid file that the SNTP daemon creates. This file contains the process ID of the current invocation of the SNTP daemon.

Restrictions:

• If /etc/sntpd.pid is a symbolic link, it must have an owning UID or GID that matches the EUID or EGID that is assigned to the SNTP daemon.

• If /etc/sntpd.pid is a hard link or the target of a hard link, users that are outside the owner or group of the directory in which /etc/sntpd.pid is stored cannot have write access to the directory. Additionally, write access to /etc/sntpd.pid must be limited to the owning UID or group, for example, --w--w---- permissions.

Steps for starting SNTPD from the z/OS UNIX shell

You can start SNTPD from the z/OS UNIX shell.

Before you begin

Ensure the existence of the following files. The files used by z/OS UNIX SNTPD and their locations in the z/OS UNIX file system are as follows:

/etc/services
The ports for each application are defined here.

/etc/syslog.conf
The configuration parameters for usage of syslogd are defined in this file.

/usr/sbin/sntpd
This is a symbolic link to /usr/lpp/tcpip/sbin/sntpd, which is a sticky-bit file. The SNTPD member of SEZALOAD contains the executable code for the SNTP server.

/usr/lib/nls/msg/C/sntpdmsg.cat
The message catalog used by the z/OS UNIX SNTPD server.

When restricting low port usage, the port used by SNTPD (default value of 123) should either:
• Be reserved for the name of the SNTPD start procedure
• Use the SAF parameter on the PORT statement to restrict access to the SNTPD port

There is no configuration file specifically for SNTPD.

Procedure
Type sntpd & on the command line.
This command starts SNTPD and sends it to the background. The following optional parameters are used for the sntpd command:

-\texttt{d}
  Enables debugging. Debug messages go to syslog daemon.

-\texttt{df} \texttt{pathname}
  Enable debugging. Debug messages go to the specified file location.

-\texttt{pf} \texttt{pathname}
  Path for pid file. For example:
  \begin{verbatim}
  -pf /var
  \end{verbatim}

-\texttt{m} \texttt{nnnnn}
  Acts in multicast mode. Sends multicast updates (TTL=1) on all interfaces every \texttt{nnnnn} seconds. Listens to multicast requests and responds with unicast replies. The valid range for -m is 1 to 16284.

-\texttt{b} \texttt{nnnnn}
  Acts in broadcast mode. This parameter sends local broadcasts on all interfaces every \texttt{nnnnn} seconds. It also specifies to listen to broadcast requests and respond with unicast replies. The valid range for -b is 1 to 16284.

-\texttt{s} \texttt{nn}
  Use \texttt{nn} as the stratum level in all replies sent by the server. The valid range for \texttt{nn} is 1 to 15. If -s is not specified or a value is specified that is not valid, the default stratum level of 1 is used. The stratum level indicates the relative accuracy of the local clock compared to the clocks of other SNTP servers in the network. The value 1 is most accurate and 15 is least accurate.

-? Display the syntax of the command usage and options.

Results
You know that SNTPD has started when the following message appears on the MVS console:

\begin{verbatim}
EZZ9600I SNTP SERVER READY.
\end{verbatim}

Steps for starting SNTPD as a procedure
You can start SNTPD as an MVS started procedure.

Before you begin
Obtain a copy of this sample procedure from SEZAINST and store it in one of your PROCLIB concatenation data sets.

Procedure
Invoke the procedure using the system operator start command.
The following sample, SEZAINST(SNTPD), shows how to start SNTPD as a procedure:

\begin{verbatim}
//SNTPD
PROC
/*
//
Results

You know that SNTPD has started when the following message appears on the console:

EZZ9600I SNTP SERVER READY.

Stack affinity

If you are running in a multiple stack environment and want SNTPD to use only a single stack, the environment variable _BPXK_SETIBMOPT_TRANSPORT can be used.
Chapter 29. Remote Execution

This topic describes how to configure and operate both the Remote Execution server and the UNIX Remote Execution server. z/OS Communications Server supports remote execution daemons in both the UNIX and TSO environments.

To execute commands under the UNIX shell, use the RSH command. To execute commands under TSO, use the REXEC command. These requests are serviced by the UNIX daemons, orshd and orexecd, and the TSO RXSERVE daemon.

The differences between the UNIX daemons and the TSO RXSERVE daemon are as follows:
- The UNIX daemons are initiated through the INETD server and can be configured to support a port other than their well-known port.
- The TSO daemon must be active and will service REXEC and RSH requests only on their well-known ports.

Only the UNIX daemons or the TSO daemon can be active at any one time.

**UNIX REXEC**

The UNIX Remote Execution Protocol Daemon (REXECD) is the server for the REXEC routine. REXECD allows execution of z/OS UNIX commands with authentication based on user names and passwords.

The Remote Shell Server (RSHD) is the server for the remote shell (RSH) client. The server provides remote execution facilities with authentication based on privileged port numbers, user IDs, and passwords.

See “Configuring the z/OS UNIX Remote Execution servers” on page 1281 for more information about configuring this server.

**TSO REXEC**

The TSO Remote Execution server allows execution of a TSO command that has been received at a remote host. This server runs the Remote EXECution Command Daemon (REXECD) which supports both the Remote Execution (REXEC) and Remote Shell (RSH) protocols.

The TSO Remote Execution server has affinity for a specific transport in a CINET environment. Configure and execute a unique instance of the server for each TCP/IP stack requiring TSO remote execution services.

### Configuring the TSO Remote Execution server

**Procedure**

Perform the following steps to configure the TSO Remote Execution server:

1. Update AUTOLOG and PORT statements in the PROFILE.TCPIP data set.
2. Determine whether the Remote Execution client will send a Remote Execution (REXEC) command or Remote Shell (RSH) command.
3. Permit remote users to access MVS resources. (Required only if the client is not sending a password.)
4. Update the Remote Execution cataloged procedure.
5. Create a user exit routine (optional).
6. Permit access to JESSPOOL files.
Step 1: Configuring PROFILE.TCPIP for TSO Remote Execution server

If you want the Remote Execution server to start automatically when the TCPIP address space is started, include the name of the member containing the RXSERVE cataloged procedure in the AUTOLOG statement in the hlq.PROFILE.TCPIP data set.

```
AUTOLOG
RXSERVE
ENDAUTOLOG
```

To ensure that port 512 is reserved for the Remote Execution protocol and port 514 for the Remote Shell protocol, add the name of the member containing the Remote Execution cataloged procedure to the PORT statement in hlq.PROFILE.TCPIP:

```
PORT
512 TCP RXSERVE
514 TCP RXSERVE
```

See z/OS Communications Server: IP Configuration Reference for more information about the AUTOLOG and PORT statements.

Step 2: Determine whether Remote Execution client will send REXEC or RSH commands

The Remote Execution client can send commands to the TSO Remote Execution server by the following methods:

1. Sending the Remote Execution (REXEC) command
2. Sending the Remote Shell (RSH) command with a user ID and password separated by a slash (/) character with the -l option on the RSH command
3. Sending the Remote Shell (RSH) command without a password

With methods “1” on page 1278 and “2” on page 1278, the TSO Remote Execution server executes the request and passes the password to MVS for verification. (REXEC commands require a password.) When these methods are used, skip Step 3.

With method “3” on page 1278, to enable an RSH client to send RSH commands to the TSO Remote Execution server without specifying a password, Step 3 is required.

Step 3: Permit remote users to access MVS resources (optional)

This step is necessary only if your installation allows users to issue remote execution commands without the requirement of specifying a password on the remote execution client.

Procedure

Use the following steps to ensure that the server can correctly access necessary MVS resources. You can use z/OS Security Server (RACF) or an equivalent security program.

1. Verify that your system has been configured for allowing surrogate job submission as described in z/OS Security Server RACF Security Administrator’s Guide (SC28-1915) or by using an equivalent security program.
2. Authorize the TSO Remote Execution server to submit jobs for the MVS user ID specified with the -l option of the RSH command. This can be done with the RACF facility as described in z/OS Security Server RACF Security Administrator’s Guide (SC28-1915), or by using an equivalent security program.
3. Define an mvs_userid.RHOSTS.DATA data set and authorize the TSO Remote Execution server user ID permission to read this data set. This can be done with the RACF facility as described in z/OS Security Server RACF Security Administrator’s Guide (SC28-1915), or by using an equivalent security program.

Note: This is the user ID used to start the RXSERVE address space.

This data set identifies the Remote Execution clients that can execute MVS commands remotely by sending an RSH command.
When a Remote Execution client sends an RSH request to the TSO Remote Execution server, the request includes the local user ID of the client user (local_userid) and, if the client user specified the -l option of the RSH command, the request also contains the user ID to use on the remote host (mvs_userid). If the client does not specify the -l option, the user ID to be used on the remote host is assumed to be the same as the local_userid.

When the TSO Remote Execution server receives an RSH command without a password, the server looks for a data set called mvs_userid.RHOSTS.DATA. The mvs_userid.RHOSTS.DATA data set contains one or more entries. Each entry consists of two parts, a fully qualified name of the client user's host and a local_userid associated with that host. The local_userid is case sensitive. If the data set exists, the server reads it and looks for an entry with a host name that matches the client user's host. If the user ID specified on this entry in the RHOSTS.DATA data set matches the local_userid passed on the RSH command, the RSH command continues processing. If the entry does not exist, the server responds to the client with message EZA4386E Permission denied.

**Tip:** If the client connected to this host through a link-local address, the client's host name generated by the resolver can be in the format hostname%scope. Adding %scope information to the appropriate RHOSTS.DATA client host definitions results in a more efficient search for a matching client host name. For details on the support for including scope information on configured host names, see z/OS Communications Server: IPv6 Network and Application Design Guide.

In the following example of an RHOSTS.DATA data set, the MVS client user mvsuser is allowed to issue the RSH command without a password from host rs60007 with a local AIX user ID of aixuser.

Example of mvsuser.RHOSTS.DATA data set:

```
rs60007.itso.ral.ibm.com aixuser
```

**Guideline:** It is suggested not enabling the MVRSHD server. The MVRSHD server supports the RSH and REXEC protocols which transfer user ID and password information in the clear. There is also the potential of weak authentication for RSH clients using RHOSTS.DATA datasets. This authentication method allows remote command execution without requiring the RSH client to supply a password. IBM Health Checker for z/OS can be used to check whether the MVRSHD server is active and detect an RSH client attempting to use an RHOSTS.DATA dataset for authentication. For more details about IBM Health Checker, see IBM Health Checker for z/OS: User's Guide.

4. Users may be authenticated using Kerberos or GSS. If the username in the Kerberos or GSS credentials matches the local user ID (local_userid) of the client supplied by the RSH client, then no password is required.

**Step 4: Update the TSO Remote Execution cataloged procedure**

Update the TSO Remote Execution cataloged procedure by copying the sample provided in SEZAINST(RXPROC) to your system or recognized PROCLIB and modifying it to suit your local conditions. Specify the TSO Remote Execution server parameters and modify the JCL as required for your installation.

**Rule:** The PREFIX specification must be unique for every instance of RXSERVE that runs in a JESPLEX. The JESPLEX is a system that shares the same JES spool.

**Tip:** You can update the TSO Remote Execution server operating parameters during execution with the MODIFY command. All but MAXCONN, IPV6, and SECLABEL can be changed.

**Step 5: Create a user exit routine (optional)**

The TSO Remote Execution server enables you to provide an optional user exit routine. You can use this routine to alter the JOB and EXEC statement parameters. In addition, you can use this routine to provide JES control statements to meet installation-specific requirements, such as updating accounting information before the submission of the TSO batch job.

On entry to the exit, register 1 points to the following parameter list:

<table>
<thead>
<tr>
<th>Offset</th>
<th>Description</th>
</tr>
</thead>
</table>

Remote Execution 1279
A pointer to an AF_INET or AF_INET6 address structure in the following format:

<table>
<thead>
<tr>
<th>Offset</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>+0</td>
<td>Address family AF_INET or AF_INET6 (2 bytes)</td>
</tr>
<tr>
<td>+2</td>
<td>Server port (2 bytes)</td>
</tr>
<tr>
<td>+4</td>
<td>Client AF_INET or AF_INET6 IP address (4 or 16 bytes)</td>
</tr>
</tbody>
</table>

+4
A pointer to a 1024-byte string terminated by the null character (0x00), which contains the JOB statement parameters. The exit routine can modify this string to meet installation-specific requirements. On entry, the string is set to the following string:

```
userid,USER=user1,[PASSWORD=passwd,]MSGCLASS=msgclass[,SECLABEL=seclabel]
```

The `userid` and `passwd` values are set to the user ID and password that the client provides, and the `msgclass` value is the message class of the Remote Execution server cataloged procedure. The `PASSWORD` parameter is present only when the client provides a password. The server passes the `SECLABEL` parameter only when the user ID is defined with a security label. The following example shows a modified string:

```
userid,USER=USER1,PASSWORD=USERXX1,MSGCLASS=E,LINES=999999,NOTIFY=SYSADM
```

+8
A pointer to a 256-byte string terminated by the null character (0x00), which contains the EXEC statement parameters. The exit routine can modify this string to meet installation-specific requirements. On entry, the string contains the EXEC statement for the procedure that is specified on the TSOPROC parameter of the Remote Execution server, or the default IKJACCNT procedure if the TSOPROC parameter is not specified. The following example shows a modified string:

```
IKJACCNT,REGION=4K,TIME=300
```

+12
A pointer to a 256-byte string terminated by the null character (0x00), which the exit can use to provide JES control statements. On entry, the string is set to 0x00. The following example shows a modified string:

```
/*JOBPARM SYSAFF=SYS5
```

Exit return codes:

- 0
  A return code of 0 indicates to the server to continue processing the request.

- Nonzero
  A nonzero return code indicates to the server to send the job control buffer (offset +4) back to the client and close the connection.

Rules:

- Code the exit with the AMODE(31) and RMODE(ANY) attributes to ensure proper addressability of the input parameters.
- The exit must terminate all modified strings with the null character (0x00).
- If the server is IPv6 enabled and an IPv4 client connects, the IP address is the 4-byte IPv4 address and not the IPv4-mapped IPv6 address.
• If the exit provides JES control statements, the server inserts the control statements into the JCL stream following the JOB statement and before the EXEC statement without any parsing. If more than one control statement is present, the exit must ensure proper JCL line separation by including the NL character or CRLF character as necessary.

• The server inserts the EXEC parameters into the JCL stream without parsing. If the exit modifies the EXEC parameters, it must ensure proper JCL line separation by including the NL character or CRLF character as necessary.

Guidelines:
• For RSH commands without passwords, the PASSWORD parameter is not present.
• The userid in the first positional parameter of the JOB statement parameters can be processed by installation-written JES exits.
• The modified parameters are submitted as a TSO batch job.

Tip: The exit can have the server reject a connection by setting a nonzero return code. The exit can replace the JOB statement buffer contents with message text to be returned to the client. The first byte of the buffer can be set to 0x00 to reject the connection without sending a message to the client.

The user exit is shipped as a sample in the RXUEXIT member of the SEZAINST data set. For more information about this sample, see the REXEC topic in z/OS Communications Server: IP Configuration Reference.

Step 6: Permit access to JESSPOOL files

If the SAF resource class JESSPOOL is defined, ALTER access is required to access output files. Alternatively, use a jobname of prefix*, where prefix is defined in RXSERVE.

Configuring the z/OS UNIX Remote Execution servers

This topic describes the z/OS UNIX files used by z/OS UNIX REXEC and RSHD.

Files for z/OS UNIX REXEC

Note: The user ID associated with the daemon in /etc/inetd.conf requires superuser authority. See z/OS UNIX System Services Planning for a description of the kinds of authority defined for daemons.

The files used by z/OS UNIX REXEC and their locations in the z/OS UNIX file system are as follows:

/etc/services
The ports for each application are defined here.

/etc/syslog.conf
The configuration parameters for usage of syslogd are defined in this file.

/etc/inetd.conf
The configuration parameters for all applications started by inetd are defined in this file.

/usr/sbin/orexecd
The server.

If BPX.DAEMON is specified, then the sticky bit must be set on, and /usr/sbin/orexecd, and orexecd can be in an authorized MVS data set.

/usr/lib/nls/msg/C/rexdmsg.cat
The message catalog used by the z/OS UNIX REXEC server.

Note: This is not an actual member at this location, but it is a symbolic link to the part in /usr/lpp/tcpip/nls/msg/C/*.

Where the server looks for the message catalog (rexdmsg.cat) depends on the value of NLSPATH and LANG environment variables. If you want to store the msg.cats elsewhere, you need to change the NLSPATH or the LANG environment variables. If rexdmsg.cat does not exist, by default, the software...
uses the messages hard-coded within the software. These messages duplicate the English message catalog that is shipped with the product.

**Files for z/OS UNIX RSHD**

The files used by z/OS UNIX RSHD and their locations in the z/OS UNIX file system are as follows:

- **/etc/services**
  The ports for each application are defined here.

- **/etc/syslog.conf**
  The configuration parameters for usage of syslogd are defined in this file.

- **/etc/inetd.conf**
  The configuration parameters for all applications started by inetd are defined in this file.

- **/usr/sbin/orshd**
  The server.
  If BPX.DAEMON is specified, the sticky bit must be set on, and /usr/sbin/orshd, and orshd can be in an authorized MVS data set.

- **/usr/sbin/ruserok**
  An optional user exit that will authenticate users logging into the z/OS UNIX RSHD server with a null password. See “Setting up the z/OS UNIX RSHD installation exit” on page 1282 for more information.
  **Note:** This exit is required to allow support for null passwords with RSH.

- **/usr/lib/nls/msg/C/rshdmsg.cat**
  The message catalog associated with the z/OS UNIX RSHD client is stored here. If this file does not exist, by default, the software uses the messages hard-coded within the software. These messages duplicate the English message catalog that is shipped with the product.
  **Note:** The message catalog is not actually stored here. This is a symbolic link, and the actual member is in /usr/lpp/tcpip/nls/msg/C/*.

**Considerations for Kerberos authentication**

If you plan to use Kerberos authentication with z/OS UNIX RSHD, you need to ensure that the user ID under which inetd runs has permission to the ICSF callable services that Kerberos needs. Specifically, if the CSFSERV class is active, ensure that the user ID of inetd has read access to the following ICSF SAF resources:

- CSF1TRC
- CSF1SKE
- CSF1SKD
- CSF1TRD
- CSFOWH

On z/OS, Kerberos is implemented by Security Server. See z/OS Integrated Security Services Network Authentication Service Administration for more information.

**Setting up the z/OS UNIX RSHD installation exit**

When the -x option is enabled, if there is no password specified on the RSH command from the client, z/OS UNIX RSHD will drive the installation exit. When the installation exit is driven, RSHD looks for a program in /usr/sbin named ruserok. This is the only name that it will look for. If /usr/sbin/ruserok is not found, the request will fail.

When the z/OS UNIX RSHD server invokes /usr/sbin/ruserok, it will pass parameters in the following order:

1. Host name or the host IP address
2. Local user’s UID
3. Remote user ID
4. Local user ID

If z/OS UNIX RSHD receives a return code of zero from the installation exit, z/OS UNIX RSHD continues. Any nonzero return code from the installation exit will cause RSHD to issue message EZYRS25E to the
client and terminate all connections. The following code fragment can be used as an example to begin building a working ruserok installation exit:

```c
int main(argc, argv)
    int argc;
    char *argv[];
    char *rhost1;    /* "hostname" or "hostname.domain" of client
    obtained by caller:
    gethostbyaddr(getpeername()) or the host
    ip address used by the gethostbyaddr if
    it failed to return a "hostname" */
    int locuid;      /* uid of the user name on local system */
    char *cliuname;  /* user name on client's system */
    char *servuname; /* user name on this (server's) system */
    int rc = 4;
    rhost1 = argv[1];
    locuid = atoi(argv[2]);
    cliuname = argv[3];
    servuname = argv[4];
    
    /* authenticate user and set rc=0 if valid */
    return(rc);
```
2. Issue NETSTAT and it should show that both the REXEC servers are listening on port 512 and both RSH servers are listening on port 514. INETD, which listens for the z/OS UNIX Remote Execution servers, listens only on the VIPA address.

Chapter 30. Express logon services with the Digital Certificate Access Server

The Digital Certificate Access Server (DCAS) is a z/OS TCP/IP server that you can use for enhanced logon solutions for z/OS applications. DCAS is part of several IBM express logon solutions, such as Express Logon Feature (ELF) and Web Express Logon (WEL), that work with IBM's host emulation products. DCAS provides a service for these solutions (with ELF, DCAS is needed only for the 3-tier solution) by providing them with z/OS user IDs and PassTickets for logon to host applications. A PassTicket is like a password. In addition, DCAS also provides an open interface and can be used by third-party express logon solutions to obtain user IDs and PassTickets for logon to z/OS applications. Note that DCAS does not support IBM Multi-Factor Authentication for z/OS.

Express Logon Feature

Express Logon Feature (ELF) is an enhanced logon solution that is provided by IBM host access products Host on Demand (HoD) and Personal Communications. ELF is also referred to as certificate-based logon. ELF enables you to log on to host applications using an X.509 certificate for authentication. For more information, see “What DCAS provides” on page 1285 and Appendix C, “Express Logon Feature,” on page 1305.

Web Express Logon

Web Express Logon (WEL) is a single-signon solution that is provided by IBM host access products Host on Demand (HoD) and Host Access Transformation Services (HATS). WEL enables users that are already authenticated, by Web-based logon for example, to log on to their host-based applications without having to reauthenticate by entering a user ID and password. In this case, the host access product communicates with the DCAS server to obtain a PassTicket. For more information about HoD, see http://www.ibm.com/software/rational/products/hostondemand/. For more information about HATS, see http://www.ibm.com/software/awdtools/hats/.

Using the DCAS server interface for your logon solutions

DCAS provides an open interface for clients to connect using TCP/IP to obtain information that can be used in providing enhanced host logon solutions. For details on interfacing with DCAS, see z/OS Communications Server: IP Programmer’s Guide and Reference.

What DCAS provides

In general, DCAS provides a service for returning a PassTicket. A PassTicket is like a password and can be used to log on to z/OS applications. RACF provides PassTicket support using the PTKTDATA class. To understand PassTickets and using the secured signon function, see z/OS Security Server RACF Security Administrator's Guide. The type of information DCAS returns depends upon the type of information requested by the client. Also, DCAS configuration controls what type of information is allowed to be provided.

DCAS provides two types of information:

• Certificate-based

  Given an x.509 certificate and an application ID, DCAS returns the user ID that has been mapped to the certificate in RACF and a PassTicket. This can be used by logon services that want to provide certificate-
based logons. In this case, the certificate provided must be associated with a valid user ID in RACF. For information on using RACDCERT to administer certificates, see z/OS Security Server RACF Security Administrator’s Guide. This support is used by IBM’s Express Logon Feature (ELF) for the 3-tier solution.

- **User ID-based**

  Given a user ID and an application ID, DCAS returns a PassTicket. In this case, the end-user should already have been authenticated using a method such as Web-based sign on, and the logon solution provider must ensure this authentication prior to requesting the PassTicket. This support is used by IBM’s Web Express Logon (WEL).

**Requirements:**

- You must configure the DCAS server. For details on configuring DCAS, see z/OS Communications Server: IP Configuration Reference. The DCAS server must be configured to support the IBM logon solution that you want, or when using it for a general or third-party solution, must be configured to return the information that the client requires. This requires that the system administrator that is configuring DCAS and the logon service provider using DCAS work together. The SERVERTYPE configuration statement in the DCAS server profile determines the type of information that DCAS can provide to connecting clients and services (certificate-based, user ID-based, or both).

- DCAS requires that all clients must connect by using TLS/SSL and that the client must be authenticated. DCAS calls System SSL or uses AT-TLS for TLS/SSL. For more information, see “Customizing DCAS for TLS/SSL” on page 1286. Review the CLIENTAUTH parameter in the DCAS configuration profile for determining the level of DCAS client authentication. To understand how to configure SSL key rings and certificates for DCAS, see Appendix B, “TLS/SSL security,” on page 1299.

- For all supported configurations, DCAS provides a PassTicket for z/OS applications that are targets for express logon. For these applications, a PassTicket data profile must be defined. RACF provides PassTicket support using the PTKTDATA class.

### Customizing DCAS for TLS/SSL

You can customize DCAS to use IBM System SSL or implement TLS security by using AT-TLS policies.

**Before you begin**

Ensure that you have the following setup or configuration:

- A valid DCAS configuration file must be available for DCAS to start. The following list shows the search order of DCAS configuration file:
  1. DCAS_CONFIG_FILE environment variable
  2. /etc/dcas.conf
  3. tsuserid.DCAS.CONF
  4. TCPIP.DCAS.CONF

- DCAS must be enabled to support TLS/SSL. DCAS can call IBM System SSL or use AT-TLS policies. For more information about configuring SSL key rings and certificates for DCAS, see Appendix B, “TLS/SSL security,” on page 1299.

- To allow DCAS to use IBM System SSL, complete the following actions:
  - Set up the configuration for DCAS. For more information, see Express LOGON using DCAS in z/OS Communications Server: IP Configuration Reference.
  - Set the TLSMECHANISM keyword value to DCAS in the DCAS configuration file.

Using IBM System SSL is the default setting for DCAS.

- To use AT-TLS policies, set the TLSMECHANISM keyword to ATTLS in the DCAS configuration file. For more information about setting up AT-TLS for DCAS, see Steps for customizing DCAS for TLS/SSL and Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1093.
Guideline: Using AT-TLS is the preferred way to implement TLS security because it provides access to the latest features of System SSL, including the newest TLS versions and cipher suites. DCAS's direct use of System SSL is limited to TLS version 1.0 and SSL versions 3 and 2 and it does not exploit many other System SSL features that AT-TLS can.

Requirement: To use AT-TLS, you must configure the Policy Agent and enable the TCP/IP stack for AT-TLS. To configure AT-TLS, see Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1093.

Procedure

Complete the following steps to customize DCAS to use IBM System SSL or implement TLS security by using AT-TLS policies.

1. Code the following statement in the DCAS configuration file to enable the server for AT-TLS:

   ```plaintext
   TLSMECHANISM ATTLS
   ```

2. Decide the level of authentication that you use for TLS sessions:
   - Server authentication only
   - Client authentication level 1
   - Client authentication level 2
   - Client authentication level 3

   For more information about server authentication and client authentication, see “Secure Socket Layer overview” on page 1299.

3. Create the server key ring database and add the certificates that you need to the server key ring database. For more information about server authentication, see “Server authentication ” on page 1299.
   - For server authentication, because every TLS session handshake includes server authentication, you must add a certificate for this server to the server key ring database. If a server certificate is self-signed, you must also export this certificate to the key ring databases of the clients that log in by using TLS. If a server certificate is signed by a certificate authority (CA), this CA certificate, instead of the server certificate, must be in the client key ring databases. For more information about server authentication, see “Server authentication ” on page 1299.
   - For client authentication, if you use client authentication and self-signed certificates, you must import the client certificates into the server key ring database. If a client certificate is signed by a certificate authority (CA), this CA certificate, instead of the client certificate, must be in the server key ring database. For more information, see “Client authentication” on page 1300.

4. You must configure the AT-TLS policies for DCAS. For more information about configuring AT-TLS, see “Configuring the server system” on page 1098. To migrate the DCAS server from using IBM System SSL to using AT-TLS, see “Migrating the DCAS server to use AT-TLS policies” on page 1289.

   Note the following requirements for policy configuration when DCAS TLSMECHANISM is set to ATTLS:
   - You must complete the following configuration for AT-TLS policies:
     - Code the TTLSEnvironmentAdvancedParms statement with the ApplicationControlled parameter ON in the policy configuration file. The ApplicationControlled parameter enables DCAS to start TLS security on a connection.
     - Set the HandshakeRole parameter to ServerWithClientAuth on the TTLSEnvironmentAction statement in the policy configuration file.
     - Code the same level of client authentication, the CLIENTAUTH parameter, in the DCAS configuration file and AT-TLS policies, the ClientAuthType parameter.
     - The TTLSRule statement with the LocalPortRange parameter and the LocalAddr parameter must include the DCAS configured values for PORT and IPADDR.
     - Configure TTLSCipherParms statement in the policy configuration file to use ciphers.
See Digital Certificate access server (DCAS) configuration file keywords and parameters in z/OS Communications Server: IP Configuration Reference for detailed information.

<table>
<thead>
<tr>
<th>DCAS Configuration Value</th>

</tr>
<tr>
<td>IPADDR &lt;inaddrValue&gt;</td>
<td>LocalAddr &lt;include inaddrValue&gt;</td>
</tr>
</tbody>
</table>

The following Policy Agent AT-TLS configuration sample shows the required policy configuration statements for AT-TLS:

```plaintext
TTLSGroupAction secure_DCAS_group
{
  TTLSEnabled On
}

TTLSEnvironmentAction secure_DCAS_env
{
  TTLSKeyringParms
  {
    Keyring server-keyring-database  # Use Keyring or SAFKeyring
  }
  HandshakeRole ServerWithClientAuth
  TTLSEnvironmentAdvancedParms
  {
    ApplicationControlled On
    ClientAuthType SAFCHECK            # Used with CLIENTAUTH Local2
  }
  TTLSCipherParmsRef DCAS_ciphers   # Used to customize ciphersuites for DCAS
}

TTLSCipherParms DCAS_ciphers
{
  # Sample ciphers. Should be customized!
  V3CipherSuites TLS_RSA_WITH_AES_256_CBC_SHA
  V3CipherSuites TLS_RSA_WITH_3DES_EDE_CBC_SHA
  V3CipherSuites TLS_RSA_WITH_NULL_SHA
}

TTLSRule secure_DCAS_rule
{
  LocalPortRange 8990     # This should be set to the port DCAS is
  # listening on (PORT keyword in DCAS configuration file)
  Direction Inbound
  TTLSGroupActionRef secure_DCAS_group
  TTLSEnvironmentActionRef secure_DCAS_env
}
```

Tip:
- You can enable more security settings with AT-TLS, such as LDAP servers and handshake timeout values. The configuration that is used in the sample is the minimum requirement to allow the DCAS server to use AT-TLS.
- Default AT-TLS policies for DCAS are defined in the IBM Configuration Assistant for z/OS Communications Server.
5. Decide which cipher suites that the server should use to protect data transfers and control information.

DCAS and AT-TLS support TLS through the System SSL cryptographic services, which is a base element of z/OS. System SSL supports multiple cipher suites that provide encryption, data authentication, and data integrity.

- Encryption algorithms scramble the data so that the data is transferred confidentially and cannot be interpreted without a special key.
- Data authentication algorithms ensure that the data is originated from the expected sender.
- Data integrity algorithms ensure that the data is not modified during transfer.

Some of the supplied cipher suites provide only data authentication or data integrity but others also provide encryption. The cipher suite that is used for the session is determined by a negotiation between the server and client. For example, if you configure DCAS to use a list of three different cipher suites, the client chooses which of those three that the client can support based on its own configuration. The first matching suite in the list is chosen. If the client does not support any of the three suites, the negotiation fails and the secure connection is not established.

Select which cipher algorithms to use by coding a TTLSCipherParms configuration statement to specify the cipher suites that the server can use. For the cipher suites that are supported on the TTLSCipherParms statement, see z/OS Communications Server: IP Configuration Reference. List the cipher suites in the order of preference and put the most preferred cipher suite first. The cipher suite is negotiated with the server on behalf of the client by using the same order of preference as the order that the TTLSCipherParms statement indicates.

**Guideline:** The default cipher suites that System SSL uses include a null cipher, which has no encryption, authentication, or integrity. A TTLSCipherParms statement must be coded to remove the null cipher from the acceptable ciphers.

6. Configure your security product for TLS. For more information, see Appendix B, “TLS/SSL security,” on page 1299.

---

**Migrating the DCAS server to use AT-TLS policies**

You must migrate DCAS configuration files to use AT-TLS policies.

Complete the following steps to migrate the DCAS server to use AT-TLS policies:

1. Customize the DCAS server for TLS/SSL. For more information, see “Customizing DCAS for TLS/SSL” on page 1286.

2. Migrate the DCAS configuration file. For more information about DCAS configuration keywords and equivalent AT-TLS policies, see Table 74 on page 1289.

---

**Transport Layer Security (TLS) terms**

The following terms apply to Transport Layer Security (TLS).

**Partner authentication, server authentication, client authentication**
Indicates an algorithm that is applied to verify the authenticity of the TLS/SSL partner. This is done by using X.509 digital certificates. Server authentication indicates that the server authenticates itself to the client. Client authentication indicates that the client authenticates itself to the server after the server authentication completes.

**Data authentication protection, data authentication**
Indicates that an algorithm is applied to the data that is being transferred. This algorithm modifies the data so that the receiving program can verify whether the data is originated from the expected sender.

**Data integrity protection**
Indicates that an algorithm is applied to the data that is being transferred. This algorithm modifies the data so that the receiving program can verify whether the data was not modified or changed by others during the transfer.

**Privacy protection, encryption**
Indicates that an algorithm is applied to the data that is being transferred. This algorithm encrypts or scramble the data so that only the receiving program can use a special key to decrypt or unscramble the data to its original format.

The original data cannot be seen or interpreted when the data is being transferred.

**Raw**
Indicates that the data is transferred without being modified by any encryption, data authentication, or data integrity algorithms.

**Cipher suite**
A collection of partner authentication, data authentication, data integrity, and encryption algorithms, which are used in combination for a given TLS/SSL session.
**Note:** This term does not indicate the algorithms that are used and does not indicate that the data is encrypted.
Chapter 31. Miscellaneous server

The Miscellaneous (MISC) server is a server that can be used to test and debug applications. The MISC server supports the 3 protocols described in RFCs 862, 863, and 864:

- Discard
- Echo
- Character Generator

Discard protocol

The MISC server throws away any data it receives. A TCP-based server listens for TCP connections on TCP port 9. If a connection is established, the data is discarded and no response is sent. A UDP-based server listens for UDP datagrams on UDP port 9. When a datagram is received, it is discarded and no response is sent.

Echo protocol

The MISC server returns to the originating application any data that it receives. A TCP-based server listens for TCP connections on TCP port 7. After a connection is established, any data that is received is sent back to the originating application. A UDP-based server listens for UDP datagrams on UDP port 7. When a datagram is received, the data it contained is sent back as an answering datagram.

Character generator protocol

The MISC server sends a repetitive stream of character data without regard to its content. A TCP-based server listens for TCP connections on TCP port 19. When a connection is established, a stream of data is sent to the connecting application. Any data that is received is thrown away. A UDP-based server listens for UDP datagrams on port 19. When a datagram is received, an answering datagram is sent that contains a random number (between 0 and 512) of characters. The data in the received datagram is ignored.

The data that is generated follows an ordered sequence. It repeats a pattern of 94 printable ASCII characters in a ring, so that character number 0 follows character number 94.
The following example shows the repeated pattern.

Configuring the MISC server

Procedure

1. Specify AUTOLOG and PORT statements in hlq.PROFILE.TCPIP.
2. Update the MISC server cataloged procedure (MISCSERV).

Step 1: Configuring PROFILE.TCPIP for the MISC server

To allow the MISC server to start automatically when TCPIP is initialized, include the member name of the MISC server cataloged procedure in the AUTOLOG statement in the hlq.PROFILE.TCPIP.

```
AUTOLOG
MISCSERV
ENDAUTOLOG
```

The AUTOLOG entry in hlq.PROFILE.TCPIP is optional. You can choose to start the MISC server manually, when it is needed, using the START command:

```
START MISCSERV
```

The MISC server requires ports 7, 9, and 19 for both TCP and UDP. To ensure that these ports are reserved for the MISC server, verify that they are assigned to the member containing the MISC server cataloged procedure in the PORT statement in PROFILE.TCPIP.

```
PORT
  7 UDP MISCSERV
  7 TCP MISCSERV
  9 UDP MISCSERV
  9 TCP MISCSERV
  19 UDP MISCSERV
  19 TCP MISCSERV
```

For more information on these statements, see the z/OS Communications Server: IP Configuration Reference.
Step 2: Updating the MISC server cataloged procedure

Update the MISC server cataloged procedure by copying the sample in SEZAINST(MISCSERV) to your system or recognized PROCLIB and modifying the parameters and data set names to suit your local conditions.

MISC server cataloged procedure (MISCSERV)

```
/MISCSERV PROC MODULE=MISCSRV,PARMS=''
/**
 ** TCP/IP for MVS
 ** SMP/E Distribution Name: SEZAINST(MISCSERV)
 /**
 ** Licensed Materials - Program Property of IBM.
 ** "Restricted Materials of IBM"
 ** 5694-A01 (C) COPYRIGHT IBM CORP. 1994, 2003
 /**
 ** Status = CSV1R5
 /**
 ** Distribution library SEZAINST(MISCSERV)
 /**
 ** MISCSERV EXEC PGM=MISCSERV,
 ** REGION=4096K,TIME=1440,
 ** PARM='&PARMS'
 /**
 ** The C runtime libraries should be in the system's link list
 ** or add them to the STEPLIB definition here. If you add
 ** them to STEPLIB, they must be APF authorized. Change
 ** the name as appropriate for your installation.
 /**
 ** STEPLIB DD DISP=SHR,
 ** DSN=TCPIP.SEZATCP
 ** SYSPRINT DD SYSOUT=*
 ** SYSIN DD DUMMY
 ** SYSMDUMP DD SYSOUT=* 
 /**
 ** MSMISCSR identifies an optional data set for NLS support.
 ** It specifies the MISC server message repository.
 /**
 ** SYSTCPD DD DISP=SHR,
 ** DSN=TCPIP.SEZAINST(TMISC)
 /**
 ** SYSTCPD explicitly identifies which data set is to be
 ** used to obtain the parameters defined by TCPIP.DATA
 ** when no GLOBALTCPIPDATA statement is configured.
 ** See the IP Configuration Guide for information on
 ** the TCPIP.DATA search order.
 ** The data set can be any sequential data set or a member of
 ** a partitioned data set (PDS).
 /**
 ** SYSTCPD DD DISP=SHR,
 ** DSN=TCPIP.SEZAINST(TCPDATA)
```

Specifying the MISC server parameters

The MISC server generates periodic messages whenever a client sends data to ports 7, 9, or 19. If this server runs continually for a long period of time, considerable amounts of spool space can be consumed. Therefore, the MISC server has all tracing turned off by default.

You can enable the trace options for any of the three MISC server protocols using the PARMS= parameter on the PROC statement of the cataloged procedure. These options will be in effect when the server starts.

**TRACE**

Turns on tracing for any of the specified protocols and must be followed by one or more of these three keywords:

- **ECho**
  Specifies tracing for the echo protocol on port 7.

- **Discard**
  Specifies tracing for the discard protocol on port 9.

- **CHargen**
  Specifies tracing for the character generator protocol on port 19.
DEbug
Specifies tracing for problem determination.
For example, the following statement turns tracing on for the echo and discard protocols.

```
//MISCSERV PROC MODULE=MISCSRV,PARMS='TRACE ECHO DISCARD'
```
Appendix A. Setting up the InetD configuration file

The Internet Daemon (InetD) is a generic listener program that is used by such servers as the z/OS UNIX telnet server and the z/OS UNIX rexec server. Other servers such as the z/OS UNIX ftp server have their own listener program and do not use InetD. For more information about generic servers and sample InetD started procedure JCL, see “Generic servers in a CINET environment” on page 48.

The inetd.conf file is an example of the user configuration file. This file is stored in the /etc directory and is referenced as a start parameter in the InetD started procedure JCL. The inet.conf file can also be stored as an MVS data set. Ensure that you use configuration statements like those statements in the following example to enable the InetD services that are required on your system:

```
#=========================================
# service | socket | protocol | wait/ | user | server  | server program
# name    | type   |          | nowait|      | program |   arguments
#=========================================
# shell    | stream | tcp       | nowait OMVSKERN /usr/sbin/orshd orshd -l
exec     | stream | tcp       | nowait OMVSKERN /usr/sbin/orexecd orexecd -lv
otelnet  | stream | tcp       | nowait OMVSKERN /usr/sbin/otelnetd otelnetd
# Add the following line to enable Kerberos for orshd
kshell   | stream | tcp       | nowait OMVSKERN /usr/sbin/orshd orshd -l -k KRB5
```

Figure 152. Adding applications to /etc/inetd.conf

If the rshd_rexecd, or otelnetd service is to support IPv6 clients, then tcp6 should be specified instead of tcp. Kerberos is not supported for IPv6-enabled services, such as z/OS UNIX Telnet, z/OS UNIX rsh, and z/OS UNIX rexec.

For IPv4 connection partners, the terminal ID passed from InetD to RACF (or an equivalent security program) is an 8-byte hexadecimal character string containing an IPv4 address. For example, the IP address 163.97.227.17 is translated to X'A361E311'. RACF interprets this as a terminal logon address and rejects it if it is not previously defined.

For IPv6 connection partners, only IPv4-mapped IPv6 addresses are handled in this way. The IPv4 address portion of the IPv6 address is placed in the terminal ID for RACF validation. No other IPv6 address format is supported through terminal ID RACF validation.

To establish a relationship between the servers defined in the /etc/inetd.conf file and specific port numbers in the z/OS UNIX environment, ensure that statements have been added to ETC.SERVICES for each of these servers. See the sample ETC.SERVICES installed in the /usr/lpp/tcpip/samples/services directory for how to specify ETC.SERVICES statements for these servers.

The traces for both the z/OS UNIX rexec and rsh servers are enabled through options in the InetD configuration file (/etc/inetd.conf):

```
#=========================================
# service | socket | protocol | wait/ | user | server  | server program
# name    | type   |          | nowait|      | program |   arguments
#=========================================
# shell    | stream | tcp       | nowait OMVSKERN /usr/sbin/orshd orshd -l 1
exec     | stream | tcp       | nowait OMVSKERN /usr/sbin/orexecd orexecd -d 2
```

Figure 153. Setting traces in /etc/inetd.conf

The traces are turned on for both servers by passing a -d argument to the server programs. 1 is the RSHD server and 2 is the REXECD server. All commands executed after the debug flags have been turned on in the InetD configuration file and the InetD server has reread the file will produce trace output.
The trace is written in formatted form to the syslogd facility name daemon with a priority of debug. The trace data can be routed to a file in your Hierarchical File System by specifying the following definition in your syslogd configuration file (/etc/syslogd.conf):

```
# All ftp, rexecd, rshd
# debug messages (and above
# priority messages) go
# to server.debug.a
#
daemon.debug /tmp/syslogd/server.debug.a
```

In this example, the trace data is written to /tmp/syslogd/server.debug.a in your Hierarchical File System. For more information on syslogd, see “Logging of system messages” on page 30.

For more information about InetD, see z/OS UNIX System Services Planning or z/OS UNIX System Services Command Reference.
Appendix B. TLS/SSL security

The Transport Layer Security (TLS) protocol is defined by the Internet Engineering Task Force (IETF) in RFCs 2246, 4346, and 5246. TLS is based on the Secure Socket Layer (SSL) protocol. SSL is not defined by the IETF.

This appendix is a reference for z/OS Communications Server applications that use TLS/SSL.

More information about the concepts of cryptography and SSL can be found at the following websites:

- http://httpd.apache.org/docs/2.0/ssl/ssl_intro.html

For examples of digital certificate implementation scenarios, see z/OS Security Server RACF Security Administrator’s Guide.

Secure Socket Layer overview

SSL provides data privacy and integrity as well as server and client authentication based upon a Public Key Infrastructure (PKI) method. PKI requires that the server organization generate a public key/private key pair that can be used during negotiations. PKI requires that data encrypted with the public key be decrypted by only the private key and that data encrypted with the private key be decrypted by only the public key. This is considered an asymmetric encryption method because different keys are used at each end of the secure connection. The Server sends its public key to the client when the client requests a connection.

The client and server encrypt SSL parameter negotiations using the PKI method of encryption. One of the most important items negotiated is the encryption algorithm to be used during data transmission. The algorithm chosen will be one that uses the same key at each end of the secure connection. This is known as a symmetric encryption method and is about 1000 times faster than the asymmetric PKI method used during SSL parameter negotiation. The encryption key used by the symmetric encryption method is created and exchanged during SSL negotiation protected by the PKI encryption method.

Some client-server connections support negotiations to determine if the client wants or supports SSL prior to beginning the SSL handshake. Most servers and clients can be configured to immediately start the SSL handshake process or to negotiate whether or not to perform the SSL handshake. See the security information for the appropriate server or client for information on whether negotiated TLS/SSL is supported and how it is implemented.

The SSL protocol begins with the handshake. During the handshake:

- Server authentication is done by the client.
- Optional client authentication is done by the server.
- An encryption algorithm and single encryption key are chosen to encrypt and decrypt session data between the client and server.

Server authentication

When using SSL to secure communications, the SSL authentication mechanism known as Server Authentication is used. This is the minimum amount of security provided by SSL and allows the client to validate that the Server is what it says it is.

To ensure that someone has not stolen the server’s private and public keys and is pretending to be the server, the server sends additional information with the public key so the client can confirm the identity of the server. The complete package of information sent to the client is called a digital certificate which conforms to the X.509 standard.
This X.509 digital certificate includes, among other things, the Distinguished Name (DN) of the Server organization, the public key created by the server organization, the Distinguished Name of the organization issuing the certificate, and the issuer's signature. The organization issuing the certificate may be a well-known Certificate Authority (CA) or you may issue (create) your own certificate, called a self-signed certificate.

To create a signature, the certificate issuer first generates a message digest from the owner's DN, the owner's public key, and the issuer's DN. The message digest is the result of hashing this information down to a small size, such as 128, 160, 256, or some other number of bits. The message digest result is unique for that information and is based on the hashing algorithm that is used. The message digest is encrypted with the issuer's private key to create the issuer's signature.

When the client receives the server certificate, the client must have the public key of the certificate signer. The public key is used to decrypt the message digest. The server certificate also contains the hashing algorithm used to create the message digest. The client uses the same algorithm to create another message digest using the Distinguished Names and public key information in the received server certificate. If this new message digest exactly matches the decrypted message digest (issuer's signature) created by the certificate issuer, the client can be assured that the certificate has not been altered. This method of authentication is dependent on the security of the private key that is used by the certificate issuer.

To conduct commercial business on the Internet, you should obtain a server certificate signed by a well-known Certificate Authority. Server certificates issued by a well-known CA gives the client high assurance that the server is authentic. Most client key rings have been primed with several well-known CA's certificates. That enables the client to authenticate a Server certificate signed by a well-known CA without having to first obtain the issuer's certificate which includes the public key. For relatively small, private networks within your own enterprise you can create your own self-signed server certificate. The only difference between a CA issued certificate and a self-signed certificate is the issuer's Distinguished Name and who's private key was used to encrypt the message digest. The client needs to use the correct public key to decrypt the message digest. The CA certificate containing the CA's public key is probably already in the client's key ring and it can be used to decrypt the CA signature (message digest). The self-signed certificate containing the organization's public key needs to be added to the client's list of signer certificates so the client can decrypt the signature (message digest) created when the self-signed certificate was created. Some client products allow the client to add the server certificate to its list of signer certificates when the server certificate is received during SSL negotiation. If the client is confident the certificate really came from the correct server, this is an easy way to add the certificate rather than getting a copy and adding it manually.

For server authentication to work, the server must have a private key and associated server certificate in the server key database file. The gskkyman utility or RACF Common Keyring support can be used to manage the keys and certificates needed for SSL support. If the gskkyman utility was used to create the key ring, a password stash file is also required.

SSL requires a server certificate as part of its server authentication process. The server certificate and the Certificate Authority certificates are stored in a key ring (also referred to as a key database). The server's key ring can be created using the gskkyman utility provided by the System Secure Socket Layer (System SSL) element of z/OS or by using RACF's certificate management support. The key ring is associated with a server or client using server or client specific statements.

Note: Global step-up type certificates are not supported by Telnet profile defined security if the client application sends the handshake complete message to the server before completing the second handshake. AT-TLS enabled Telnet does support global step-up type certificates.

Client authentication

Client authentication provides additional authentication and access control by checking client certificates at the server. This support prevents a client from obtaining a connection without an installation approved certificate.
The server authenticates the client by receiving the client's certificate during the SSL handshake and verifying the certificate is valid. Validation is done by the server the same way the client validates the server's certificate. The client sends a signed certificate to the server. System SSL at the server decrypts the signature (message digest) using the public key of the client certificate issuer found in the server key database file. The server then creates a new message digest using the certificate's Distinguished Names and public key and compares the new message digest with the decrypted one. If they match, the server can be assured the client is authentic. Depending on where the client certificate is stored, up to three different levels of client authentication are available. See the security information for the appropriate server or client for setup details.

**Level 1** authentication is performed by System SSL. The client passes an X.509 certificate to the Server as part of the SSL Handshake. To pass authentication, the Certificate Authority (CA) that signed the client certificate must be considered trusted by the server. That is, the certificate for the CA must be in the key ring used by the Server and designated as trusted. Note that the value of this option alone is based on which CAs are considered trusted. If the CA is a public CA and the certificate is in an easily obtained class, anyone can obtain such a certificate. In this case passing level 1 SSL Client Authentication does not provide much additional security unless coupled with the level 2 RACF support. If the CA is controlled by the enterprise, some level of access control is provided because the client that possesses such a certificate is at least known to the organization.

In addition to the checking done with the first level of client authentication support, **level 2** authentication requires that the client certificate is registered with RACF or another SAF-compliant security product and is mapped to a valid z/OS user ID. The client certificate that is received during the SSL handshake is used to query the security product to verify that the certificate maps to a user ID known to the system before connection negotiation. This level of support provides extra access control at the server and ensures that the user is known to have a valid user ID on the server host. Each server uses the returned user ID in a different way. To see how the user ID is used for a particular server, see the security information for the appropriate server or client. Level 1 authentication occurs before level 2 authentication.

**Level 3** authentication provides, in addition to level 1 and level 2 support, the capability to restrict access to the server based on the user ID returned from RACF. In some cases a certificate may be valid and mapped to a user ID but should be valid for only one of several servers. The third level of control uses the SERVAUTH RACF class to restrict access to the server based on client user ID. If the SERVAUTH class is not active or the SERVAUTH profile for the server is not defined, it is assumed level 3 authentication is not requested. If the SERVAUTH class is active and the server profile is defined, a connection is accepted only if the requester's user ID associated with the client certificate is in the profile. Otherwise, the connection is dropped.

To enable Client Authentication for each server, use the following server-specific statements:

<table>
<thead>
<tr>
<th>AUTHENTICATION LEVEL</th>
<th>FTP</th>
<th>Telnet</th>
<th>DCAS</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>SECURE_LOGIN statement</td>
<td>CLIENTAUTH statement</td>
<td>CLIENTAUTH statement</td>
</tr>
<tr>
<td>AUTH LEVEL 1</td>
<td>REQUIRED</td>
<td>SSLCERT</td>
<td>LOCAL 1</td>
</tr>
<tr>
<td>AUTH LEVEL 2</td>
<td>VERIFY_USER</td>
<td>SAFCERT</td>
<td>LOCAL 2</td>
</tr>
<tr>
<td>AUTH LEVEL 3</td>
<td>VERIFY_USER</td>
<td>SAFCERT</td>
<td>LOCAL 3</td>
</tr>
</tbody>
</table>

Level 1 client authentication is done by SSL using a gskkyman key ring or a RACF key ring. If the client certificate was issued by a well-known Certificate Authority, it is likely the CA certificate is already primed in the gskkyman key ring. The CA certificate is probably also in RACF. However, all CA certificates in RACF initially have a status of NOTRUST. The CA certificate must be set to TRUST and connected to the appropriate RACF key ring. If the certificate issuer (a CA or self-signed) is not part of the list of well-known CAs, the key ring must be primed with the signer certificate of the CA or the self-signed client certificate.

After Level 1 authentication is performed by SSL using either key ring, the certificate is passed to the server which accesses the RACF database for Level 2 and Level 3 authentication.
Encryption algorithms

After authentication occurs, the client and server must agree on a symmetric encryption method and generate a single encryption key to use for data encryption. The chosen key is exchanged by using the PKI method of encryption. After the symmetric encryption algorithm (such as AES) and a single encryption key are chosen, all data exchanges use this algorithm and key instead of the PKI method of encryption.

In an SSL-encrypted session, all data is encrypted with the symmetric encryption algorithm immediately before it is sent to the client. Data from the client is decrypted immediately after it is received. The encryption algorithm that is used for the connection depends on a combination of the following factors:

- The encryption algorithm list that the SSL subsystem supports
- The list that the server wants to use
- The encryption algorithms that the client requests

During the SSL handshake, the client sends a list of encryption algorithms it is able to use. The server submits its list and the SSL subsystem picks an algorithm that all parties support, giving preference to the order that the server specifies. If the server does not support any of the encryption algorithms that the client requests, the connection is closed. Several z/OS Communications Server applications use the SSL support that is provided by the System Secure Sockets Layer (System SSL) element of z/OS. The encryption algorithms that the servers and client support depend on the level of System SSL that is installed. The following encryption algorithms are supported by the base level of System SSL:

- NULL
- RC2 export
- RC4 export
- DES

The System SSL Level 3 feature is required for Triple DES, AES, and RC4 non-export (128 bit) encryption algorithms. The encryption algorithm list can be customized for the servers and client to a subset of the System SSL list. For specific server and client statements that are used to create the encryption list, see the security information for the appropriate server or client.

Encryption is provided by either hardware, if available, or software algorithms within System SSL or Integrated Cryptographic Services Facility (ICSF). There is no TCP profile definition to control whether the cryptographic hardware is used for secure connections. For information about cryptographic hardware usage within System SSL, see z/OS Cryptographic Services System SSL Programming. To use FIPS 140 mode, ICSF must be started and available to System SSL.

If hardware encryption is to be used, be sure that the RACF user ID associated with the server has read access to the RACF CSFSERV class resources. If ICSF is available but the server has not been given access to these resources, the SSL initialization may fail. The reason code is likely to be 4 (bad password) because System SSL will attempt to use the hardware encryption during processing of the key ring.

Enable CSFSERV resources

If hardware encryption and Integrated Cryptographic Services Facility (ICSF) are installed, system SSL verifies that the user ID that is associated with the server is permitted to use CSFSERV resources. The RACF administrator can permit the RACF user ID to use the CSFSERV resources:

```
PERMIT service-name CLASS(CSFSERV) ID(serverid) ACCESS(READ)
```

For information about the CSFSERV resources (service-names) that are accessed by System SSL, see z/OS Cryptographic Services System SSL Programming.

z/OS FTP users can either permit every FTP client user ID to these general resource profiles, or they can mark these profiles as delegated and permit only the FTP daemon user ID to the profiles.
In the following example, resource CSFENC in class CSFSERV is delegated, and only the FTP daemon user ID (FTPD for this example) needs to be permitted. Make these changes before you start FTPD.

Permit the FTP daemon to the resource:

```
PERMIT CSFENC CLASS(CSFSERV) ID(FTPD) ACCESS(READ)
```

Mark the resource profile as delegated:

```
RALTER CSFSERV CSFENC APPLDATA('RACF-DELEGATED ')
```

Refresh the CSFSERV class:

```
SETROPTS RACLIST(CSFSERV) REFRESH
```

For more examples, see the EZARACF sample in SEZAINST. For more information about authorizing daemons to use delegated resources, see z/OS Security Server RACF Security Administrator's Guide.

The MAXLEN installation option for hardware cryptography determines the maximum length that can be used to encrypt and decrypt data by using ICSF. Set this option to 65527 or greater, which is the maximum TCP/IP packet size.

The System SSL GSKSRVR server provides the capability to determine whether cryptographic hardware is being used through its DISPLAY CRYPTO operator command (for example, f gsksrvr,d crypto). The System SSL GSKSRVR server is not automatically started. For more information about the SSL started task and setting up and using the GSKSRVR server, see z/OS Cryptographic Services System SSL Programming.

For more information about controlling who can use cryptographic keys and services, see z/OS Cryptographic Services ICSF Administrator's Guide.
Appendix C. Express Logon Feature

Users accessing SNA applications using Telnet clients such as Host On Demand are generally required to know the user ID and password for the application they want to access. The ID-and-password authentication process creates several potential problems. For example, users may forget their IDs and passwords. If they do forget, the passwords must be reset by a system administrator, a time-consuming process. On the other hand, writing down the IDs and passwords or sharing them with someone else creates a security risk, especially because passwords are usually valid for relatively long periods of time.

IBM’s solution to these problems is the Express Logon Feature (ELF), a process which allows a user on a workstation with a Telnet client and an X.509 certificate to log on to an SNA application without entering an ID or password. The Express Logon Feature is supported on two-tier and three-tier network designs. The two-tier design uses the z/OS TN3270E Telnet server. The three-tier design uses a middle-tier Telnet server and a Digital Certificate Access Server (DCAS).

Figure 154. Express Logon network

Both network designs require a Telnet client emulator that supports:

- Transport Layer Security (TLS) or Secure Sockets Layer (SSL) connections with client authentication and an X.509 certificate. Using RACF services in z/OS, the client certificate must be associated with a valid user ID.
- The Express Logon Feature (ELF).

The two-tier design requires the z/OS TN3270E Telnet server with TLS/SSL, client authentication, and Express Logon functions turned on. See “Express Logon Feature” on page 615 for server setup information.

The three-tier design requires a middle-tier Telnet server that includes a Digital Certificate Access Requester (DCAR) and the z/OS Digital Certificate Access Server (DCAS). A middle-tier Telnet server, so called because it is not on the host, but rather between the Telnet client emulator and the host.

Note: The term DCAR is used to describe the part of the Telnet middle-tier server that supports the Express Logon Feature and communicates as a client with the DCAS. It is not separate from the Telnet middle-tier server. The term DCAR might not be used in other information that describes ELF but has been used here to simplify the description of this function.

A Digital Certificate Access Server (DCAS) exists on the host. DCAS uses RACF services to obtain a user ID that has been mapped to a digital certificate.
The host also provides RACF Secured Signon services, which the DCAS or the z/OS host TN3270E Telnet server uses to generate a PassTicket. A PassTicket is a RACF token similar to a password except that it is valid only for ten minutes. Additionally, the z/OS TN3270E Telnet server might use a Multi-Factor Authentication (MFA) token that was generated by IBM MFA for z/OS.

In a typical scenario, an ELF-enabled client wants to log on to a TSO application on the host.

- In the two-tier design, the user starts a secure connection with level 2 client authentication, which passes the client certificate to the TN3270E Telnet server. The TN3270E Telnet server uses either RACF MFA services to retrieve a user ID and an MFA token or uses RACF Secured Signon services to obtain a user ID and PassTicket.
- In the three-tier design, the user starts the Telnet connection to the middle-tier Telnet server. The client of the DCAS is the middle-tier Telnet server or DCAR, which attempts to log on to an SNA application for the client emulator. The DCAS receives a digital certificate from the DCAR and returns a user ID and PassTicket. Secure communication is used between the DCAS and the DCAR. The server recognizes that the client wants the Express Logon function and invokes the DCAR, which opens a secure connection with client authentication and passes the client’s certificate and application name to the DCAS on the host. The DCAS uses RACF Secured Signon services to obtain a user ID and PassTicket, which the DCAS returns to the DCAR. The DCAR passes this information back to the middle-tier Telnet server.

In both cases the ELF-enabled client and server now have enough information to complete the logon to TSO. This occurs without the user ever having to enter a user ID or password.

**Note:** You can use RACF or any other SAF-compliant security product that supports MFA (for the two-tier design) or PassTickets with Express Logon.

### Configuring RACF services for Express Logon

At a minimum, you must register all client certificates with RACF or create a RACF certificate name filter for the client certificates by using the RACDCERT command. This associates the certificates with the IDs of users who are attempting to log on. In the two-tier solution, the certificate is passed from the client to the TN3270E Telnet server. In the three-tier solution, the certificate is passed from the client to the middle-tier Telnet server, then to the DCAR, and then to the DCAS.

### Configuring RACF and IBM Multi-Factor Authentication for z/OS (two-tier solution only)

To use IBM Multi-Factor Authentication (MFA) for z/OS, you must set up and configure the IBM MFA for z/OS product and also add appropriate MFA parameters to the RACF user profile for the users that need to log in with MFA tokens. For more information about IBM MFA for z/OS setup and configuration, see the following documentation:

- **IBM MFA V1R1: TouchToken, PassTicket, and Application Bypass Support** (An IBM Redpaper publication: IBM Form #: REDP-5386)
- **z/OS Security Server RACF Security Administrator’s Guide**
- **IBM Multi-Factor Authentication for z/OS Installation and Customization**

### Configuring RACF for PassTickets

You must also create a RACF PTKTDATA profile for each application ID the user is attempting to access. The PTKTDATA profile allows the DCAS or z/OS TN3270E Telnet server to obtain a PassTicket and user ID for the application. In the three-tier solution, the DCAS must pass the PassTicket and user ID back to the DCAR. For Host On Demand, the application ID part of the profile name must be the same as that configured in the Host On Demand Express Logon Application ID popup window. In most cases, the application name with which the user logs on will match the application ID portion of the RACF PTKTDATA class profile. However, for TSO and some other applications, the names and IDs may not match:

- If VTAM generic resources are used for TSO, define the application name portion on the RACF profile using the TCASGNAM defined in the TSOKEYxx, SYS1.PARMLIB member.
- If VTAM generic resources are not used, define the application name on the RACF profile as TSO.
• When configuring for TSO application logon, use the format TSO<SID> in the PassTicket profile, where SID is the SMF system ID defined in the SMFPRMxx member of SYS1.PARMLIB. (For example, if the SID is 3390, you would type TSO3390 in the profile.) For details, see z/OS Security Server RACF Security Administrator’s Guide.

For applications that allow shared user IDs (multiple users request access to the application simultaneously with the same user ID), you must specify the APPLDATA('NO REPLAY PROTECTION') option on the RDEFINE command in the PTKTDATA profile. This bypasses the default RACF protection against replay of PassTickets.

**An example of configuring the Express Logon components**

The following example describes, in general terms, how to set up and configure Express Logon by using the following products and components:

- IBM Host On Demand Telnet client
- z/OS TN3270E Telnet server (for two-tier solution)
- IBM Communications Server for Windows (middle-tier Telnet server for three-tier solution)
- DCAS - see Chapter 30, “Express logon services with the Digital Certificate Access Server,” on page 1285

For details on configuring each product, see the appropriate documentation for that product.

**Configuring the Host On Demand Telnet client**

To setup and configure the Host On Demand client, follow these steps:

1. For each application to which the user will log on, create a macro to record the logon screen of the application.
   
   The user plays this macro when displaying the logon screen on the client.

2. Enter the application ID in the application ID popup window.
   
   The application ID must be the same name specified on the z/OS for the application ID portion of the PTKTDATA profile. The ID in the profile in most cases must be the same as the application name.

3. Use the Host On Demand key-management utility to:
   
   a. Create a key database (key ring).
   
   b. Create a certificate request or generate a self-signed certificate and associate the certificate with the key ring.
   
   c. Use FTP to transmit the middle-tier Telnet certificate to the client workstation and store the server certificate in the key database of the client.
   
   d. Use FTP to transmit the Host On Demand Telnet client certificate to the middle-tier server and store in the SSL key database of the server.

4. Use FTP to transmit the client certificate to an MVS data set on the z/OS host. Use the RACF Certificate Services RACDCERT command to associate the certificate with a valid user ID.

**Configuring the z/OS TN3270E Telnet server (two-tier solution)**

Express Logon Feature requires TLS/SSL with level 2 client authentication functionality at the server. After that level of security is working, specify the EXPRESSLOGONMFA (to use Multi-Factor Authentication tokens) or EXPRESSLOGON (to use PassTickets) parameter statement to enable ELF in the z/OS TN3270E Telnet server.
Configuring the middle-tier Telnet server (IBM Communications Server for Windows example)

The middle-tier server is a Telnet server such as IBM Communications Server for Windows, that communicates with the Host On Demand client using a TLS/SSL connection with client authentication. The middle-tier server DCAR also communicates with the DCAS on the host. The DCAS and DCAR communicate over a TCP/IP connection using TLS/SSL with client authentication.

To configure the Telnet server, follow these steps:

1. Use the Communications Server for Windows SNA Node Configuration panels to enable the Express Logon Feature and configure the DCAS server address and port.
2. Use the local key management utility to store the client certificate and the DCAS certificate in the local key ring:
   a. Create a key database file.
   b. Create a certificate request or generate a self-signed certificate and associate the certificate with the key ring.
   c. Store the client certificate and the DCAS certificate in the key ring of the server.
3. Use FTP to transmit the DCAR certificate to the z/OS host and use gskkyman or RACF Certificate Services to store the DCAR certificate in the DCAS key ring.
Appendix D. Using HCD

This information includes examples of panels that are used to define IQD channels and devices for z/OS Communications Server using HCD.

1. Select processors

![Select processors panel](image_url)

*Figure 155. Select processors*

2. Select 'S' Work with attached channel paths
3. On the Channel Path List enter the Add command (or press F11) to initiate the Define Channel Path dialog.
Figure 157. Initiate the Define Channel Path dialog

4. Fill in the Add Channel Path panel, then press Enter (Select SHR for Operation mode to share IQD Chpids across LPARs).
5. For an IQD channel path, the Specify Maximum Frame Size panel pops up with the default value of 16 KB.
Figure 159. Specify Maximum Frame Size

Or change the frame size to wanted size:

<table>
<thead>
<tr>
<th>Maximum Frame Size</th>
<th>TCP/IP MTU size</th>
</tr>
</thead>
<tbody>
<tr>
<td>16K</td>
<td>8K</td>
</tr>
<tr>
<td>24K</td>
<td>16K</td>
</tr>
<tr>
<td>40K</td>
<td>32K</td>
</tr>
<tr>
<td>64K</td>
<td>56K</td>
</tr>
</tbody>
</table>

6. Define the channel path access list that each LPAR should have access to.
Figure 160. Define the channel path access list

7. Having pressed Enter, the Channel Path List is redisplayed with channel path number FF defined.
Figure 161. Channel path number FF defined

8. As the next step, add the control unit(s) to the IQD channel path. Select the defined channel path with action "Work with attached control units" (action code 'S').
9. An empty control unit list is displayed. Enter the 'Add' command or F11.
Figure 163. Add the control unit(s)

10. Define a control unit of type 'IQD' for channel path FF.
Figure 164. Define a control unit

11. Define it to the processor:
12. The processor settings are already preset. Pressing Enter, returns to the Select Processor/Control unit panel. Pressing Enter again, returns to the Control Unit List panel which shows the currently defined control unit.
13. Next, define the devices. Successively, select a control unit and perform action "Work with attached Devices".

**Figure 166. Currently defined control unit**

<table>
<thead>
<tr>
<th>Specification</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Control unit number</td>
<td>DD00</td>
</tr>
<tr>

</tr>
</tbody>
</table>

F1=Help  F2=Split  F3=Exit  F4=Prompt  F5=Reset  F9=Swap  F12=Cancel
Figure 167. Define the devices

14. This leads to an empty device list.
15. Perform the Add action to define the devices for the control unit selected in the previous step.
16. Add devices of type IQD to the selected control unit.
17. If the number of devices has been left unspecified (as in this example), HCD defines 10 devices.
Figure 171. Define number of devices

18. Hit enter and the next panel displayed will be:
19. Next, define the devices to the operating system by selecting an 'S' on each system you want to have them defined on.

*Figure 172. Define device to operating system*
Figure 173. Select systems

20. The device parameters are shown with default values. Press Enter, to complete the definition for each system.
21. Press Enter until you return to the I/O device list panel, the definition for channel path FF is complete.
The sample IOCP input for this example would be:

```
CHPID PATH=(FF),SHARED, * 
PARTITION=((LPAR1,LPAR2,LPAR3),(LPAR1,LPAR2,LPAR3)), * 
TYPE=IQD,OS=00 
CNTLUNIT CUNUMBR=DD00,PATH=(FF),UNIT=IQD 
IODEVICE ADDRESS=(DD00,010),CUNUMBR=(DD00),UNIT=IQD
```
Appendix E. Steps for preparing to run IP security

To run IP security, you need to configure the IKE daemon. Each step is described in detail in the corresponding subtopic.

**Procedure**

Perform the following steps to prepare to run the IKE daemon:

1. Set the appropriate UNIX System Services parameters.
2. Ensure the IKE daemon's user ID has enough system resources.
3. Authorize the IKE daemon to the external security manager.
4. Authorize the `ipsec` command to the external security manager.
5. Authorize IP security to ICSF (optional).
6. Set up the IKE daemon for RSA signature mode authentication (optional).

**Step 1: Setting appropriate UNIX System Services parameters**

Verify that AF_UNIX and AF_INET are defined in the BPXPRMxx member of SYS1.PARMLIB. If the domains are not defined, see z/OS UNIX System Services Planning for the steps to customize the BPXPRMxx parmlib member.

**Step 2: Ensure the IKE daemon's user ID has enough system resources**

The user ID under which the IKE daemon runs requires sufficient system resources when all the z/OS system's IKE peers attempt to negotiate or renegotiate IPSec tunnels with z/OS at the same time. If thousands of IKE peers attempt to negotiate or renegotiate, you might need to adjust certain system parameters upwards to ensure that IKED does not run out of critical resources. Ensure that IKED does not run out of the following critical resources:

- Virtual storage
- System message queue space
- UDP queue capacity

Follow the instructions in this section to ensure that the IKE daemon's user ID has sufficient resources.

**Virtual storage capacity**

Take the following steps to ensure the user ID has enough virtual storage:

- Adjust the REGION parameter to ensure that the TSO/E region size (REGION) for the IKE daemon user ID is at least 1 GB.
- Set the BPXPRMxx parmlib member by using the MAXASSIZE parameter to ensure that ASSIZEMAX in the OMVS segment for your user profile is at least 1 GB.
- Set the MEMLIMIT value in your OMVS segment, or set the BPXPRMxx or the SMFPRMxx parmlib members to ensure that the MEMLIMIT value for the user ID is at least 1 GB. The default value is 2 GB.

You can see the format of the `RACF ALTUSER` command when the command is issued to assign the storage allocations for a user. The MEMLIMIT value is set in the OMVS segment for the user.

```
ALU user-name TSO(SIZE(1048576)) OMVS(ASSIZEMAX(1073741824) MEMLIMIT(1G))
```
For more information about the MEMLIMIT system parameter, see z/OS MVS Programming: Extended Addressability Guide. For information about the ulimit command, see z/OS UNIX System Services Command Reference.

**System message queue capacity**

The IKE daemon uses internal OMVS message queues to route work to various threads in the process. In environments with a large number of IKE peers, the number of messages on these queues might grow significantly, to the point where the default maximum number of messages allowed on a message queue is exceeded. In such environments, set the IPCMSGQMNUM parameter of the SETOMVS command to a high value to accommodate scenarios where large numbers of SAs are being negotiated simultaneously. For more information about the IPCMSGQMNUM parameter, see z/OS MVS System Commands.

**UDP queue capacity**

If UDPQUEUELIMIT is configured or defaulted in the TCPIP profile, a UDP queue limit is in effect for the TCP/IP stack. When large numbers of IKE peers are negotiating SAs with z/OS, the limit can be exceeded. Thus, some remote IKE peers retransmit messages to z/OS and the duration of the SA negotiations increases. In such cases, you can use the UDP Traffic Regulation function of z/OS Communications Server's Intrusion Detection Services (IDS) to increase the UDP queue limit for the IKE daemon's UDP queues. Specifically, define a UDP traffic regulation rule for ports 500 and 4500 with the queue limit value set to VERY_LONG. For more information about UDP Traffic Regulation, see Traffic regulation policies for UDP ports.

**Step 3: Authorizing the IKE daemon to the external security manager**

You need to authorize the IKE daemon to the external security manager.

To authorize the IKE daemon to RACF, perform the steps in “Steps for authorizing the IKE daemon to RACF” on page 1332.

**Steps for authorizing the IKE daemon to RACF**

The commands used to authorize the IKE daemon to RACF are in EZARACF in the SEZAINST data set.

**Procedure**

Perform the following steps to authorize the IKE daemon to RACF:

1. Add user ID IKED, and add IKED to the STARTED class.
   - If IKED is defined using UID 0:
     ```
     ADDUSER IKED DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(0) HOME(’/’))
     RDEFINE STARTED IKED.* STDATA(USER(IKED))
     PERMIT BPX.DAEMON CLASS(FACILITY) ID(IKED) ACCESS(READ)
     SETROPTS RACLIST(STARTED) REFRESH
     SETROPTS GENERIC(STARTED) REFRESH
     ```
   - If IKED is defined using a nonzero UID (for example, 300) and IKE GID (for example, 931), then IKED needs the following access:
     ```
     ADDGROUP IKE OMVS(GID(931))
     ADDUSER IKED DFLTGRP(IKE) OMVS(UID(300) HOME(’/var/ike/’) NOPASSWORD
     CONNECT IKED GROUP(IKE) UACC(READ)
     RDEFINE STARTED IKED.* STDATA(USER(IKED))
     PERMIT BPX.DAEMON CLASS(FACILITY) ID(IKED) ACCESS(READ)
     SETROPTS RACLIST(STARTED) REFRESH
     SETROPTS GENERIC(STARTED) REFRESH
     ```
   a. Set the /var directory access to all using the following command:

     ```
     chmod 777 /var
     ```
b. If the /var/ike directory does not already exist, use a superuser ID to create it and modify this directory using the following commands:

```bash
mkdir /var/ike/
chown IKED /var/ike
chgrp IKE /var/ike
chmod 770 /var/ike
```

c. If the /var/sock/ directory does not already exist, use a superuser ID to create it and set the access to all using the following commands:

```bash
mkdir /var/sock/
chown 0 /var/sock
chmod 777 /var/sock
```

d. Define RACF definitions for IKED to retrieve IP security policies from Policy Agent:

```rxml
RDEFINE SERVAUTH EZB.PAGENT.sysname.*.IPSEC UACC(NONE)
PERMIT EZB.PAGENT.sysname.*.IPSEC CLASS(SERVAUTH) ID(IKED) ACCESS(READ)
SETROPTS RACLIST(SERVAUTH) REFRESH
SETROPTS GENERIC(STARTED) REFRESH
```

e. Permit IKED to issue console messages directly without the BPXM023I message prefix:

```rxml
RDEFINE FACILITY BPX.CONSOLE UACC(NONE)
PERMIT BPX.CONSOLE CLASS(FACILITY) ID(IKED) ACCESS(READ)
SETROPTS RACLIST(FACILITY) REFRESH
```

2. Allow the IKED to access SYS1.PARMLIB as follows:

```bash
PERMIT SYS1.PARMLIB ID(IKED) ACCESS(READ)
```

3. Enable the IKED to access certificates by issuing the appropriate commands.
   • If the certificates used by the IKED are not site certificates, enable the IKED to access the certificates on an ESM key ring by issuing the following commands:

```rxml
RDEFINE FACILITY IRR.DIGTCERT.LISTRING UACC(NONE)
RDEFINE FACILITY IRR.DIGTCERT.LIST UACC(NONE)
PERMIT IRR.DIGTCERT.LISTRING CLASS(FACILITY) ID(IKED) ACCESS(READ)
PERMIT IRR.DIGTCERT.LIST CLASS(FACILITY) ID(IKED) ACCESS(READ)
SETROPTS RACLIST(FACILITY) REFRESH
```

   • If the certificates used by the IKED are site certificates, enable the IKED to access them by issuing the following commands:

```rxml
RDEFINE FACILITY IRR.DIGTCERT.LISTRING UACC(NONE)
RDEFINE FACILITY IRR.DIGTCERT.LIST UACC(NONE)
RDEFINE FACILITY IRR.DIGTCERT.GENCERT UACC(NONE)
PERMIT IRR.DIGTCERT.LISTRING CLASS(FACILITY) ID(IKED) ACCESS(UPDATE)
PERMIT IRR.DIGTCERT.LIST CLASS(FACILITY) ID(IKED) ACCESS(READ)
PERMIT IRR.DIGTCERT.GENCERT CLASS(FACILITY) ID(IKED) ACCESS(CONTROL)
SETROPTS RACLIST(FACILITY) REFRESH
```

4. Enable the IKED to run as nonswappable.
   If you have defined the BPX.STOR.SWAP resource to RACF, you can enable the IKED using the following commands:

```bash
PERMIT BPX.STOR.SWAP CLASS(FACILITY) ID(IKED) ACCESS(READ)
SETROPTS RACLIST(FACILITY) REFRESH
```

**Step 4: Authorizing the ipsec command to the external security manager**

You need to authorize the `ipsec` command to the external security manager.

To authorize the `ipsec` command to RACF, perform the steps in “Steps for authorizing the ipsec command to RACF” on page 1334.
For more information about `ipsec` command security and the SERVAUTH profile, see z/OS Communications Server: IP System Administrator's Commands.

**Steps for authorizing the ipsec command to RACF**

The commands used to authorize the `ipsec` command are in EZARACF in the SEZAINST data set.

**Procedure**

Perform the following steps to authorize the `ipsec` command to RACF:

1. Define access control for the `ipsec` command.

   The `ipsec` command uses both display and control features. You can control access to each feature independently.
   
   - To control access to both the display and control capabilities of the `ipsec` command, issue the following commands:
     
     ```bash
     SETROPTS GENERIC(SERVAUTH)
     RDEFINE SERVAUTH EZB.IPSECCMD.sysname.tcpprocname.* UACC(NONE)
     PERMIT EZB.IPSECCMD.sysname.tcpprocname.* CLASS(SERVAUTH) ID(userid) ACCESS(READ)
     SETROPTS GENERIC(SERVAUTH) REFRESH
     ```
   
   - To control access specifically to the display capabilities of the `ipsec` command for a stack, issue the following commands:
     
     ```bash
     RDEFINE SERVAUTH EZB.IPSECCMD.sysname.tcpprocname.DISPLAY UACC(NONE)
     PERMIT EZB.IPSECCMD.sysname.tcpprocname.DISPLAY CLASS(SERVAUTH) ID(userid) ACCESS(READ)
     ```
   
   - To control access specifically to the display capabilities of the `ipsec` command for global defensive filters, issue the following commands:
     
     ```bash
     RDEFINE SERVAUTH EZB.IPSECCMD.sysname.DMD_GLOBAL.DISPLAY UACC(NONE)
     PERMIT EZB.IPSECCMD.sysname.DMD_GLOBAL.DISPLAY CLASS(SERVAUTH) ID(userid) ACCESS(READ)
     ```
   
   - To control access specifically to the control capabilities of the `ipsec` command for a stack, issue the following commands:
     
     ```bash
     RDEFINE SERVAUTH EZB.IPSECCMD.sysname.tcpprocname.CONTROL UACC(NONE)
     PERMIT EZB.IPSECCMD.sysname.tcpprocname.CONTROL CLASS(SERVAUTH) ID(userid) ACCESS(READ)
     ```
   
   - To control access specifically to the control capabilities of the `ipsec` command for global defensive filters, issue the following commands:
     
     ```bash
     RDEFINE SERVAUTH EZB.IPSECCMD.sysname.DMD_GLOBAL.CONTROL UACC(NONE)
     PERMIT EZB.IPSECCMD.sysname.DMD_GLOBAL.CONTROL CLASS(SERVAUTH) ID(userid) ACCESS(READ)
     ```

   **Tip:** These SERVAUTH profiles provide `ipsec` command access to only the local stack. For information about SERVAUTH profiles for controlling `ipsec` command access for the network security services (NSS) server, see “Network security services for the IPSec discipline” on page 170.

2. To refresh the in-storage RACF profiles in the SERVAUTH class, issue the following command:

   ```bash
   SETROPTS RACLIST(SERVAUTH) REFRESH
   ```
**Step 5: Authorizing IP Security to ICSF (optional)**

IP security can take advantage of the encryption and decryption functions that are available on System z hardware in the following ways:

- Encrypting and decrypting TCP/IP packet data in an IPSec tunnel.
- Encrypting signature data included as part of IKE message flows. This encryption is performed only when digital signature authentication is requested.

This encryption support is provided by the combination of the Integrated Cryptographic Feature (ICRF) on the processor and the Integrated Cryptographic Service Facility/MVS (ICSF) software product. ICSF provides cryptography support through various cryptographic hardware features. The cryptographic features that are available to your applications depends on your processor or server model. For information about which features are available on your hardware, see the information about callable service support by hardware configuration in z/OS Cryptographic Services ICSF Overview.

To use this support, ICSF must be started and running. Preferably, start ICSF prior to starting TCP/IP. However, it can also be started when TCP/IP is active. For details on configuring ICSF, see z/OS Cryptographic Services ICSF Administrator's Guide. ICSF provides SAF controls that you can optionally use to restrict access to these cryptographic services. To view a sample procedure for generating the corresponding SAF profiles for various CSFSERV services, see the Cryptographic Services Authorization section of the EZARACF sample in the SEZAINST data set.

**Requirement:** If you plan to control access to the ICSF cryptographic support, TCP/IP must be permitted to access the ICSF cryptographic services (CSFSERV).

**Guideline:** If you do not have any reason to restrict access to the ICSF cryptographic support, you should not activate the CSFSERV resource class, define any of the profiles listed below, or permit users to these profiles. If you do need to set up controls in the CSFSERV resource class, complete the steps below to enable use of ICSF for IP security.

### Steps for Setting up Profiles in the CSFSERV Resource Class

Use these steps to control access to the ICSF cryptographic support.

#### Procedure

Perform the following steps to set up profiles in the CSFSERV resource class:

1. Determine the SAF profiles that you will use within the CSFSERV resource class:
   a) You must permit the IKED and the NSSD to the CSFIQF profile.
   b) If you have CP Assist for Cryptographic Function (CPACF) enabled on your processors and you want to take advantage of it, you must have ICSF started but you do not need to grant permission to any SAF profiles.
   c) If you do not have CPACF enabled, but you do have a cryptographic coprocessor, to take advantage of it you must perform the following steps:
      1) Permit TCP/IP to the following profiles:
         - CSFCKI
         - CSFCKM (used only for Triple DES)
         - CSFDEC1
         - CSFENC1
         - CSFOWH1
      2) Permit the IKED and the NSSD to the following profiles:
         - CSFDSG
         - CSFDSV
d) If you are using AES encryption in TCP/IP for manual or dynamic tunnels, you must permit TCP/IP to the following profiles:
   • CSFDEC1
   • CSFENC1

e) If you are using AES encryption in the IKED for dynamic tunnels, you must permit the IKED to the following profiles:
   • CSFDEC
   • CSFENC

f) If you are using SHA2 or AES-XCBC authentication in TCP/IP, you must permit TCP/IP to the following profiles:
   • CSF1HMG
   • CSF1TRC
   • CSF1TRD
   • CSFMGN1

g) If you are using SHA2 or AES-XCBC authentication in the IKED, you must permit the IKED to the following profiles:
   • CSF1HMG
   • CSF1TRC
   • CSF1TRD
   • CSF0WH

h) If you are using Diffie-Hellman groups 19, 20, or 21 in the IKED, you must permit the IKED to the following profiles:
   • CSF1DVK
   • CSF1GAV
   • CSF1GKP
   • CSF1TRC
   • CSF1TRD

i) If you are using digital signature authentication in the IKED, you must permit the IKED to the following profiles:
   • CSFDSG
   • CSFDSV
   • CSFPKI

j) If you are using digital signature authentication in the NSSD, you must permit the NSSD to the following profiles:
   • CSF1HMG
   • CSF1TRC
   • CSF1TRD
   • CSFDSG
   • CSFDSV
   • CSFMGN
   • CSF0WH
   • CSFPKI
k) If you are using elliptic curve signature authentication in the NSSD, you must permit the NSSD to the following profiles:
- CSF1GAV
- CSF1PKS
- CSF1PKV

l) If you have enabled FIPS 140 support in TCP/IP, you must permit TCP/IP to the following profiles:
- CSF1HMG
- CSF1SKD
- CSF1SKE
- CSF1TRC
- CSF1TRD
- CSFRNG

m) If you have enabled FIPS 140 support in TCP/IP and you are using manual tunnels, the z/OS Communications Server Policy Agent must be permitted to the CSF1TRC profile.

n) If you have enabled FIPS 140 support in the IKED, you must permit the IKED to the following profiles:
- CSF1DMK
- CSF1DVK
- CSF1HMG
- CSF1SKD
- CSF1SKE
- CSF1TRC
- CSF1TRD
- CSFOWH

2. Define the appropriate profiles in the CSFSERV class:

   RDEFINE CSFSERV profile-name UACC(NONE)

3. Give TCP/IP access to the appropriate profiles:

   PERMIT profile-name CLASS(CSFSERV) ID(stackname) ACCESS(READ)

4. Give the userids associated with IKED, NSSD, and Policy Agent access to the appropriate resource profile in the CSFSERV class:

   PERMIT profile-name CLASS(CSFSERV) ID (userid)

5. Activate the CSFSERV class and refresh the in-storage RACF profiles:

   SETROPTS CLASSACT(CSFSERV)
   SETROPTS RACLIST(CSFSERV) REFRESH

6. Set the MAXLEN ICSF installation option to 65535 or greater because this is the maximum TCP/IP packet size. The MAXLEN installation option for hardware cryptography determines the maximum length that can be used to encrypt and decrypt data using ICSF.

---

**Step 6: Setting up the IKE daemon for digital signature authentication (optional)**

You can configure the IKE daemon to use its own certificate service or to use the certificate service from a network security services (NSS) server. You can control whether to use the native certificate service or the NSS certificate service at the stack level. A single stack can use either the native certificate service or the...
NSS certificate service, but it cannot use both. If the IKED is to use an IKEv2 signature-based authentication method on behalf of a stack, that stack must be defined as a network security services (NSS) client.

By default, the IKE daemon uses the native certificate service for all stacks. Certificates for stacks configured to use the native certificate service must be on the key ring specified by the KeyRing parameter of the IkeConfig statement.

The IKE daemon native certificate service does not consult certificate revocation information when it authenticates a digital signature. If you want revocation checking, then direct the IKED to use the IPSec certificate service of an NSS server and enable revocation checking for the remote security endpoint. For information about enabling revocation checking for a remote security endpoint using the KeyExchangeAction statement, see z/OS Communications Server: IP Configuration Reference.

The IKE daemon can be directed to use an NSS server’s certificate service for an individual stack by specifying the Cert option on the ServiceType parameter of an NssStackConfig statement for that stack. The NssStackConfig statement is specified in the IKE daemon configuration file. The NSS server does not have to be on the same system as the IKE daemon. The location of the NSS server is specified by the NetworkSecurityServer parameter and optionally the NetworkSecurityServerBackup parameter of the IkeConfig statement. For more information about the IkeConfig statement, see z/OS Communications Server: IP Configuration Reference.

Certificates for stacks configured to use an NSS server for certificate service must be on the key ring specified on the KeyRing parameter of the NssConfig statement in the NSS server configuration file. For more information about the NssConfig statement, see z/OS Communications Server: IP Configuration Reference.

Figure 176 on page 1339 shows a partial configuration for the IKE daemon on system SYSTEMA and an NSS server. The NetworkSecurityServer parameter on the IkeConfig statement specifies that the IKE daemon is configured to use network security services from an NSS server that is listening on IP address 9.1.1.1. Two NssStackConfig statements are shown. The ClientName parameters associate a local TCP/IP stack with an NSS client name. This is the name by which the NSS server knows this stack. The UserId parameter associates the client name with a user ID defined on the NSS server’s system. Both the client name and user ID are used by the NSS server to verify that an NSS client is authorized to request certificate service, and to determine what certificates the client is authorized to use (For additional details, see “Steps for authorizing resources for NSS” on page 1058). The KeyRing parameter on the IkeConfig statement identifies the location of certificates for all stacks for which there are no NssStackConfig statements. The KeyRing parameter on the NssConfig statement identifies the location of certificates for all NSS client stacks that use the NSS server certificate service.
The following subtopics provide steps for setting up the IKE daemon for RSA signature mode authentication:

- When the native certificate service is used
- When the certificate service of an NSS server is used

**Tip:** Use the following references to understand the concepts that are involved in using digital certificates with RACF:

- For more information about RACF key rings and digital certificates, see [z/OS Security Server RACF Security Administrator's Guide](https://www.ibm.com).  
- For more information about controlling the use of the RACDCERT command, see [z/OS Security Server RACF Security Administrator's Guide](https://www.ibm.com).  
- For a complete description of the facilities and authorizations that are needed to create and modify digital certificates and key rings, see [z/OS Security Server RACF Command Language Reference](https://www.ibm.com).

### Steps for setting up the IKE daemon for digital signature authentication when the native certificate service is used

You can configure the IKE daemon to use its own certificate service and to use RSA signature mode authentication. Details for each step are in the corresponding subtopics.

**Procedure**

Perform the following steps to set up the IKE daemon for digital signature authentication when the native certificate service is being used:
1. Define RACF facilities and access controls.
2. Define profiles to control access to the RACDCERT command.
3. Create a RACF key ring for the user ID under which the IKED is to run.
4. Install an X509 digital certificate to be used by the native IKE certificate service.

**Step 1: Define RACF facilities and access controls**

**Procedure**

To support RSA signature mode authentication in phase 1 negotiations, perform the following steps to give the IKE daemon the required access to a RACF key ring:

1. If they are not already defined, create the definitions that are required to allow certificates to be stored and accessed from the RACF database by issuing the following TSO commands:

   ```
   RDEFINE FACILITY IRR.DIGTCERT.LISTRING UACC(NONE)
   RDEFINE FACILITY IRR.DIGTCERT.LIST UACC(NONE)
   ```

2. To permit the IKED to the facilities, issue the following TSO commands:

   ```
   PERMIT IRR.DIGTCERT.LIST CLASS(FACILITY) ID(IKED) ACC(READ)
   PERMIT IRR.DIGTCERT.LISTRING CLASS(FACILITY) ID(IKED) ACC(READ)
   ```

3. Refresh the FACILITY class:

   ```
   SETROPTS RACLIST(FACILITY) REFRESH
   ```

**Step 2: Define profiles to control access to the RACDCERT command**

**Before you begin**

The RACF database provides digital certificate and key ring support through the RACDCERT command. The administrator who is responsible for managing the RACF key ring for the IKED needs appropriate access to this command.

**Procedure**

Perform the following steps to define profiles to control access to this command:

1. If they are not already defined, create the definitions that are required to control access to the basic RACDCERT actions by issuing the following TSO commands:

   ```
   RDEFINE FACILITY IRR.DIGTCERT.ADD UACC(NONE)
   RDEFINE FACILITY IRR.DIGTCERT.ADDRING UACC(NONE)
   RDEFINE FACILITY IRR.DIGTCERT.CONNECT UACC(NONE)
   RDEFINE FACILITY IRR.DIGTCERT.GENCERT UACC(NONE)
   RDEFINE FACILITY IRR.DIGTCERT.GENREQ UACC(NONE)
   ```

2. Issue the following TSO commands (where userid is the ID of the person who will be executing the RACDCERT command to manage digital certificates):

   ```
   PERMIT IRR.DIGTCERT.ADD CLASS(FACILITY) ID(userid) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.ADDRING CLASS(FACILITY) ID(userid) ACC(UPDATE)
   PERMIT IRR.DIGTCERT.CONNECT CLASS(FACILITY) ID(userid) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.GENCERT CLASS(FACILITY) ID(userid) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.GENREQ CLASS(FACILITY) ID(userid) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.LIST CLASS(FACILITY) ID(userid) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.LISTRING CLASS(FACILITY) ID(userid) ACC(UPDATE)
   ```

3. Refresh the FACILITY class:

   ```
   SETROPTS RACLIST(FACILITY) REFRESH
   ```
Step 3: Create a RACF key ring for the user ID under which the IKED is to run

Digital certificates are made available to the IKE daemon by connecting them to a key ring that is owned by the IKE daemon. To create a key ring for the IKE daemon, issue the following TSO command:

```
RACDCERT ID(IKED) ADDRING(ikeyring)
```

The value used for `ikeyring` is case sensitive.

Step 4: Install an X509 digital certificate to be used by the native certificate service

The procedure for installing a digital certificate on a SAF key ring for the native certificate service to use is similar to the procedure for installing a digital certificate on a SAF key ring for the NSS certificate service to use. For details, see “IPSec certificate management” on page 1342.

Steps for setting up the IKE daemon for digital signature authentication using the certificate service of an NSS server

You can configure the IKE daemon to use the certificate service of an NSS server and to use RSA signature mode authentication. Details for each step are in the corresponding subtopics.

Procedure

Perform the following steps to set up the IKE daemon for digital signature authentication when the certificate service of an NSS server is being used:

1. Update the IKE daemon configuration file to define NSS clients.
2. Install X509 digital certificates for NSS clients on the NSS server's key ring.
3. Authorize the NSS clients.
4. Enable HTTP Certificate Lookup (optional)

Step 1: Update the IKE daemon configuration file to define NSS clients

The IKE daemon configuration file must be updated to include the NetworkSecurityServer parameter and optionally the NetworkSecurityServerBackup parameter on the IkeConfig statement. These parameters identify the location of the NSS server. In addition, an NssStackConfig statement with a ServiceType value Cert must be added for each stack that will use the NSS certificate service. For additional details about configuring the IKE daemon, see z/OS Communications Server: IP Configuration Reference.

Step 2: Install X509 digital certificates for NSS clients on the NSS server's key ring

This step must be performed on the system where the NSS server will run.

The procedure for installing a digital certificates on a SAF key ring to be used by the NSS server is similar to the procedure used for installing a digital certificate on a SAF key ring for use by the native certificate service. For details, see “IPSec certificate management” on page 1342.

Step 3: Authorize the NSS clients

This step must be performed on the system where the NSS server will run.

NSS clients defined in the IKE daemon configuration file must be authorized to use the NSS server's certificate service. For authorization details, see step “7” on page 1059.

Step 4: Enable HTTP Certificate Lookup (optional)

The following actions occur during a phase 1 IKE exchange:

- Peers exchange encoded certificate information in certificate payloads
- The NSS server provides the IKED with certificate information to send
- The IKED forwards the encoded certificate information that it received from the NSS server

IKEv2 defines two new encoding types that require the use of an HTTP server:
The NSS server supports these new encoding types; however, by default the IKED does not support sending or receiving them.

Use the CertificateURLLookupPreference parameter on the KeyExchangePolicy and KeyExchangeAction statements in the IP security policy configuration file to enable the IKED to use the hash and URL encoding types. Code the appropriate value on the CertificateURLLookupPreference parameter:

- Disallow, which is the default value, indicates that the IKED will not send the new encoding type and will ignore the new encoding type when received.
- Tolerate indicates that the IKED will not send the new encoding type, but it will accept the new encoding type when received.
- Allow indicates that the IKED may send the new encoding type and it will accept the new encoding type when received.

**Rule:** You must configure the NSS server appropriately before the IKED can send the new encoding types. Enabling this capability might result in smaller messages being exchanged between the IKED and its remote security endpoint as well as the IKED and the NSS server; however, it may also result in increased latency during an IKEv2 negotiation.

For more details about the CertificateURLLookupPreference parameter on the KeyExchangePolicy and KeyExchangeAction statements, see z/OS Communications Server: IP Configuration Reference. For more details about configuring the NSS server to use the new certificate encoding types, see “Using hash and URL certificate encoding types” on page 1071.

**IPSec certificate management**

The IKE daemon and NSS server require the ability to retrieve digital certificates from a RACF key ring, each associated with a particular identity, and also to perform operations with the associated private key. The IKED can own multiple certificates on its RACF key ring. The NSS server can own multiple certificates for multiple NSS clients (that is, stacks). You can install an X509 digital certificate in the following ways:

- Generate an X509 digital certificate and have it signed by a certificate authority.
- Generate a self-signed X509 digital certificate.
- Migrate an existing key database to a RACF key ring.

**Steps for generating an X509 digital certificate and having it signed by a certificate authority**

The IKE daemon and NSS server require the ability to retrieve digital certificates associated with a particular identity from a RACF key ring, and to perform operations with the associated private key.

**Before you begin**

Assume that you have an X509 digital certificate that has the X500 distinguished name CN=SYSTEMA STACK1, OU=Inventory, O=IBM, C=US and the domain name ibm.com. The certificate identifies the local IKE daemon that executes on z/OS with the user ID IKED.

**Tip:** If you are creating a certificate for a stack configured to use the certificate service from an NSS server, issue these commands against the RACF database for the system on which the NSS server runs. Modify the user ID in the examples to be the user ID that is running the NSS server and modify the key ring to be the key ring that is configured in the NSS server's configuration file.

**Procedure**

Perform the following steps to install the X509 digital certificate:

1. Generate a self-signed certificate for the server:

   ```
   RACDCERT ID(IKED) GENCERT SUBJECTSDN(CN('SYSTEMA STACK1') OU('Inventory') O('IBM') C('US')) WITHLABEL('SYSTEMA STACK1') ALTNAME(DOMAIN('ibm.com'))
   ```
2. Take one of the following actions:
   - RACF supplies certificates for many commercial certificate authorities. If you are using one of these supplied certificate authority certificates, follow the steps for supplied digital certificates in z/OS Security Server RACF Security Administrator's Guide.
   - If the certificate authority you are using is not one of the supplied certificate authorities, obtain the root certificate of the certificate authority that is to sign the certificate of the IKED, and place it in an MVS data set (for example, USER1.EXTCA1.CERT). Add it to the RACF database as follows:

   ```
   RACDCERT ID(IKED) ADD('USER1.EXTCA1.CERT') WITHLABEL('External CA') CERTAUTH
   ```

3. Create a certificate request to send to the chosen certificate authority.
   The certificate request that you create is based on the certificate that was created in step 1. Place this certificate into a data set called USER1.SYSTEMA.STACK1.GENREQ as follows:

   ```
   RACDCERT ID(IKED) GENREQ(LABEL('SYSTEMA STACK1')) DSN('USER1.SYSTEMA.STACK1.GENREQ')
   ```

4. Send the certificate request to the certificate authority.
   The certificate request is in base 64-encoded text. Typically, the request is sent to the certificate authority by cutting and pasting the certificate request into an email that is sent to the certificate authority.

   The certificate authority validates the certificate. If the certificate is approved by the certificate authority, it is signed by the certificate authority and returned to the requester.

5. Receive the returned certificate into a data set (for example, USER1.SYSTEMA.STACK1.CERT).
   The returned certificate is in base 64-encoded text. This can be done by cutting and pasting, with FTP, or with another technique.

6. Replace the self-signed certificate with the certificate that is signed by the certificate authority.
   The certificate is replaced only if the user ID that is specified as the ID value on the RACDCERT ADD command is the same user ID that was specified when the certificate was created. Ensure that the user ID is the same. Otherwise, the certificate is added, rather than replacing the self-signed certificate, and does not contain the certificate's private key.

   ```
   RACDCERT ID(IKED) ADD('USER1.SYSTEMA.STACK1.CERT') WITHLABEL('SYSTEMA STACK1')
   ```

7. Connect the certificate to an existing key ring:

   ```
   RACDCERT ID(IKED) CONNECT(LABEL('SYSTEMA STACK1')) RING(ikeyring) USAGE(PERSONAL)
   ```

8. Connect the certificate authority's certificate to the key ring:

   ```
   RACDCERT ID(IKED) CONNECT(CERTAUTH LABEL('External CA') RING(ikeyring) USAGE(CERTAUTH))
   ```

   This completes the certificate hierarchy from root to SYSTEMA STACK1.

9. Add the following statement to the IKE daemon configuration file, iked.conf, or the NSS server configuration file, nssd.conf:

   ```
   Keyring  IKED/ikeyring
   ```

**Results**
You know you are done when the X509 digital certificate is available, and is mapped to the X500DN identity CN=SYSTEMA STACK1,OU=Inventory,O=IBM,C=US from the certificate's subject name, and the FQDN identity ibm.com from the certificate's alternate subject name.
You can verify that the certificates that you have created are connected to the key ring associated with user ID IKED by using the RACDCERT command and examining the output of the Ring Associations field. Verify that the certificate authority was created and added to the IKED/ikeyring as follows:

```
RACDCERT CERTAUTH LIST(LABEL('External CA'))
```

Verify that the personal certificate for the IKE daemon was created and added to the IKED/ikeyring as follows:

```
RACDCERT ID(IKED) LIST(LABEL('SYSTEMA STACK1'))
```

**Requirement:** If the certificates connected to the key ring are for an NSS client, you must create a SERVAUTH profile for each certificate. You must give the user ID associated with the NSS client access to this profile. Create this profile in the RACF database for the system on which the NSS server runs. For details about these profiles, see “Steps for authorizing resources for NSS” on page 1058.

**Steps for generating a self-signed X509 digital certificate**
The IKE daemon and NSS server require the ability to retrieve digital certificates associated with a particular identity from a RACF key ring, and to perform operations with the associated private key.

**Before you begin**
The certificate that is assigned to the secure server is a locally-signed certificate rather than one signed by a certificate authority. Assume that the local certificate authority has the distinguished name of OU='Local Certificate Authority', O=IBM, C=US.

**Requirement:** If you are creating a certificate for a stack configured to use the certificate service from an NSS server, issue these commands against the RACF database for the system on which the NSS server runs. The user ID in the examples must be the user ID running the NSS server and the key ring must be the key ring configured in the NSS server’s configuration file.

**Procedure**
Perform the following steps to implement a locally signed server certificate:

1. Generate a self-signed certificate to represent the local certificate authority:

```
RACDCERT CERTAUTH GENCERT SUBJECTSDN(OU('Local Certificate Authority') O('IBM') C('US'))
KEYUSAGE(CERTSIGN) WITHLABEL('IBM Local Certificate Authority')
```

This certificate is used as the certificate authority certificate.

2. Export the certificate to a data set (in this case, USER1.LOCCERTA.CERT):

```
RACDCERT CERTAUTH EXPORT(LABEL('IBM Local Certificate Authority')) DSN('USER1.LOCCERTA.CERT')
```

3. Create a certificate for the server that is signed with the certificate authority certificate that was created in step 1:

```
RACDCERT ID(IKED) GENCERT SUBJECTSDN(CN('SYSTEMA STACK1') OU('Inventory') O('IBM') C('US'))
WITHLABEL('SYSTEMA STACK1') ALTNAME(DOMAIN('ibm.com'))
SIGNWITH(CERTAUTH LABEL('IBM Local Certificate Authority'))
```

4. Connect the certificate to an existing key ring:

```
RACDCERT ID(IKED) CONNECT(LABEL('SYSTEMA STACK1') RING(ikeyring) USAGE(PERSONAL))
```

5. Connect the local certificate authority certificate to the key ring:

```
RACDCERT ID(IKED) CONNECT(CERTAUTH LABEL('IBM Local Certificate Authority') RING(ikeyring) USAGE(CERTAUTH))
```

This completes the certificate hierarchy from root to SYSTEMA STACK1.
6. Add the following statement to the IKE daemon configuration file, iked.conf, or the NSS server configuration file, nssd.conf:

| Keyring | IKED/ikeyring |

**Results**

You know you are done when the X509 digital certificate is available, and is mapped to the X500DN identity CN=SYSTEMA STACK1,OU=Inventory,O=IBM,C=US from the certificate's subject name, and the FQDN identity ibm.com from the certificate's alternate subject name.

You can verify that the certificates that you have created are connected to the key ring associated with user ID IKED by using the RACDCERT command and examining the output of the Ring Associations field. Verify that the certificate authority was created and added to the IKED/ikeyring as follows:

```
RACDCERT CERTAUTH LIST(LABEL('IBM Local Certificate Authority'))
```

Verify that the personal certificate for the IKE daemon was created and added to the IKED/ikeyring as follows:

```
RACDCERT ID(IKED) LIST(LABEL('SYSTEMA STACK1'))
```

**Requirement:** If the certificates connected to the key ring are for an NSS client, you must create a SERVAUTH profile for each certificate. You must give the user ID associated with the NSS client access to this profile. Create this profile in the RACF database for the system on which the NSS server runs. For details about these profiles, see “Steps for authorizing resources for NSS” on page 1058.

**Steps for migrating an existing key database to a RACF key ring**

The IKE daemon and NSS server require the ability to retrieve digital certificates associated with a particular identity from a RACF key ring, and to perform operations with the associated private key.

**Before you begin**

To migrate an existing key database file to a RACF key ring, see the information on migrating key database files to RACF key rings in z/OS Cryptographic Services System SSL Programming.

**Procedure**

Perform the following steps to migrate keys and certificates that are stored in an existing z/OS key database into a RACF key ring:

1. Using gskkyman, export the certificate and private key to a password-protected PKCS#12 file. For details on copying a certificate with its private key, see z/OS Cryptographic Services System SSL Programming.
2. Copy the newly created PKCS#12 file to an MVS data set.
3. Use the RACDCERT command with the ADD operand to define a certificate and private key. The data set name that was created in step 2 contains the certificate.
4. Use the RACDCERT command with the ADDRING operand to create a new key ring in RACF.
5. Use the RACDCERT command with the CONNECT operand to add the certificate and private key to one or more existing RACF key rings.
Appendix F. Using an LDAP server for policy definitions

Lightweight Directory Access Protocol (LDAP) is a fast-growing technology for accessing common directory information. LDAP has been embraced and implemented in most network-oriented middleware. As an open, vendor-neutral standard, LDAP provides an extendable architecture for centralized storage and management of information that needs to be available for today's distributed systems and services.

**Note:** If the z/OS LDAP server is used, a Db2 backend is required.

**Policy object model overview**

Policies consist of several related objects. The main object is the *policy rule*. A policy rule object refers to one or more *policy condition*, *policy action*, or *policy time period condition* objects, and also contains information on how these objects are to be used. Policy time period objects are used to determine when a given policy rule is active. Active policy objects are related in a way that is analogous to an 'IF' statement in a program. For example:

```
IF condition THEN action
```

In other words, when the set of conditions referred to by a policy rule are TRUE, then the policy actions associated with the policy rule are executed.

![Diagram of policy objects](image)

**Figure 177. Basic policy objects**

Policy rules can refer to one or more policy conditions. A policy rule with a single policy condition is known as a *simple* rule, and one with more conditions is known as a *complex* rule. Complex policy rules can have their conditions evaluated according to one of two different methods. The first is Disjunctive Normal Form (DNF), which means an ORed set of ANDed conditions. The second is Conjunctive Normal Form (CNF), which means an ANDed set of ORed conditions. In order to accomplish these evaluations, individual policy conditions are assigned an arbitrary group number, and also an indication of whether or not the condition is negated. For example, consider the following set of conditions for a policy rule:

```
C1:  Group Number = 1, Condition Negated = FALSE
C2:  Group Number = 1, Condition Negated = TRUE
C3:  Group Number = 1, Condition Negated = FALSE
```
If the conditions are to be evaluated using DNF, then the overall condition for the policy rule is:

\[(C1 \text{ AND } \neg C2 \text{ AND } C3) \text{ OR } (C4 \text{ AND } C5)\]

On the other hand, if CNF is used to evaluate the conditions, then the overall condition for the policy rule is:

\[(C1 \text{ OR } \neg C2 \text{ OR } C3) \text{ AND } (C4 \text{ OR } C5)\]

Complex rules can be split into multiple simple rules. Negated conditions are not allowed in a rule if explosion is to be performed. Consider the following set of conditions for a policy rule:

\[C1: \text{ Group Number = 1, Condition Negated = FALSE}\]
\[C2: \text{ Group Number = 1, Condition Negated = FALSE}\]
\[C3: \text{ Group Number = 1, Condition Negated = FALSE}\]
\[C4: \text{ Group Number = 2, Condition Negated = FALSE}\]
\[C5: \text{ Group Number = 2, Condition Negated = FALSE}\]

If DNF is used to evaluate the conditions, splitting the complex rule produces the following simple rules:

Simple Rule 1:  C1 AND C2 AND C3
Simple Rule 2:  C4 AND C5
If CNF is used to evaluate the conditions, splitting the complex rule produces the following simple rules:

<table>
<thead>
<tr>
<th>Simple Rule 1:</th>
<th>C1 AND C4</th>
</tr>
</thead>
<tbody>
<tr>
<td>Simple Rule 2:</td>
<td>C1 AND C5</td>
</tr>
<tr>
<td>Simple Rule 3:</td>
<td>C2 AND C4</td>
</tr>
<tr>
<td>Simple Rule 4:</td>
<td>C2 AND C5</td>
</tr>
<tr>
<td>Simple Rule 5:</td>
<td>C3 AND C4</td>
</tr>
<tr>
<td>Simple Rule 6:</td>
<td>C3 AND C5</td>
</tr>
</tbody>
</table>

Policy actions specify actions to take when the set of conditions for a policy rule evaluate to TRUE. The policy model allows multiple actions for a policy rule. Many policy rules typically use only a single action, but multiple actions make sense for some policy types.

Policy conditions and actions can either be specific to a single rule, or be reusable among several policy rules. To allow either type of conditions and actions, and to specify related information such as condition group number and negation indicator, several other policy objects are required. First are policy condition association and policy action association objects. These objects contain condition and action related attributes, respectively, and may directly contain policy conditions and actions (rule-specific).

![Figure 180. Rule-specific conditions and actions](image)

The policy association objects alternatively may refer to conditions and actions (reusable). Policy condition instance and policy action instance objects are used to represent reusable policy conditions and actions, respectively.
Primarily for administrative grouping of policy rules, the policy group object is used. Policy groups can refer either to policy rules or to policy groups. This allows related policy rules to be grouped together, and also allows policy groups to be grouped to any needed level of nesting.
Overview of the object classes

Policies defined on an LDAP server are comprised of one or more objects, each with a defined object class, and a unique name. Object names are in the form of LDAP Distinguished Names (DNs), which are text strings composed of individual parts known as Relative Distinguished Names (RDNs). The structure of the naming defines a hierarchical tree, in a manner similar to directories in a hierarchical file system. For example, consider the following set of objects:

<table>
<thead>
<tr>
<th>Object</th>
<th>DN</th>
</tr>
</thead>
<tbody>
<tr>
<td>Object 1</td>
<td>o=IBM, c=US</td>
</tr>
<tr>
<td>Object 2</td>
<td>cn=group_1, o=IBM, c=US</td>
</tr>
<tr>
<td>Object 3</td>
<td>cn=group_5, o=IBM, c=US</td>
</tr>
<tr>
<td>Object 4</td>
<td>cn=group_1_sub_A, cn=group_1, o=IBM, c=US</td>
</tr>
</tbody>
</table>

This set of objects can be viewed as a tree, with Object 1 as the root. Objects 2 and 3 are branches under the root, with Object 4 a branch under Object 2. The names used are attributes of the objects they define. For example, Object 2, whose name starts with "cn=group_1" contains a cn attribute with the value group_1. See z/OS IBM Tivoli Directory Server Administration and Use for z/OS for more information on LDAP naming.

Object class names define the type of each LDAP object. The top object class is predefined and is the root of all other object classes.

There are three types of object classes.

**Abstract object classes**
- Used to define broad concepts, such as policy and to define basic attributes that apply to all subclasses.

**Structural object classes**
- Basic building blocks, and are the only type of object class that can be instantiated as real objects on an LDAP server.

**Auxiliary object classes**
- Used to define attributes that are shared among different structural object classes, or are used to extend the basic set of objects.

Attributes from auxiliary classes are attached to structural objects by including them in the structural objects, and also by including the auxiliary object class as one of the values of the objectClass attribute in the structural object.

The following object classes are recognized by the Policy Agent. The indentation defines subclasses. For example, ibm-policyGroup is a subclass of ibm-policy, and therefore inherits all of the attributes defined for ibm-policy.
Figure 183. LDAP schema object class hierarchy

Note: The classes identified in bold italics in Figure 183 on page 1352 are for schema version 2 and are mutually exclusive with the schema version 3 classes with similar names.

<table>
<thead>
<tr>
<th>Object class name</th>
<th>Purpose of object</th>

<tr>
<td>-------------------------------------------------------</td>
<td>----------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td>ibm-policySubtreesPtrAuxClass</td>
<td>Defines an auxiliary class to represent pointers to subtrees in the LDAP directory tree to be retrieved by the Policy Agent. This allows entire subtrees to be retrieved at once, improving retrieval performance in some situations.</td>
</tr>
<tr>
<td>ibm-policyGroupContainmentAuxClass</td>
<td>Defines an auxiliary class for binding a policy group object to another policy group.</td>
</tr>
<tr>
<td>ibm-policyRuleContainmentAuxClass</td>
<td>Defines an auxiliary class for binding a policy rule object to another policy group.</td>
</tr>
<tr>
<td>ibm-policyGroupLoadDistributionAuxClass</td>
<td>Defines an auxiliary class to represent load distribution attributes for policy groups. The load distribution attributes are applied to all policy rules that are pointed to by groups to which this auxiliary class has been attached.</td>
</tr>
<tr>
<td>SetSubnetPrioTosMask</td>
<td>Defines a mapping of outbound IPv4 packet Type of Service (ToS) byte or IPv6 packet Traffic Class values to QDIO device priorities and Virtual LAN (VLAN) user priorities.</td>
</tr>
</tbody>
</table>

Policy objects are used to accomplish the following objectives:

- Group related objects together. Policy groups can contain related policy rules, and can also contain other policy groups. This allows objects to be grouped in various administrative ways. If the resulting objects will be retrieved by any Policy Agent prior to z/OS Communications Server V1R2, then the object should not include the values ibm-policyGroupContainmentAuxClass, ibm-policyRuleContainmentAuxClass or ibm-policyGroupLoadDistributionAuxClass for the objectClass attribute.

- Specify conditions for a policy rule. The conditions are used to filter traffic packets, and can specify attributes such as source and destination port, application name, protocol, and so on. Policy rules can be either simple or complex, depending on the nature of the specified conditions. When a single condition is specified, the rule is a simple rule. This single condition can be composed of any of the condition attributes, but only one instance of each. For example, only a single destination port range can be specified in a simple rule. Complex rules specify more than one condition. The specified conditions are organized into one or more levels, and each level is composed of one or more conditions. Each condition can be composed of one instance of any of the condition attributes. The conditions can thus be thought of as a two-dimensional array. Any individual condition can be negated. Two types of processing are applied to the conditions, depending on the specified condition list type:
  - Disjunctive Normal Form (DNF). DNF conditions are logically ANDed at each level, and ORed between levels.
  - Conjunctive Normal Form (CNF). CNF conditions are logically ORed at each level, and ANDed between levels.

For example, suppose five conditions are specified, two at one level and three at another:

<table>
<thead>
<tr>
<th>Level 1: C1, NOT C2</th>
</tr>
</thead>
<tbody>
<tr>
<td>Level 2: C3, C4, C5</td>
</tr>
</tbody>
</table>

If DNF is specified, the conditions are evaluated as:

(C1 AND NOT C2) OR (C3 AND C4 AND C5)
CNF evaluation of the same conditions is:

\[(C_1 \lor \neg C_2) \land (C_3 \lor C_4 \lor C_5)\]

This allows a wide variety of conditional logic to be defined for policy rules.

- Specify time periods during which policy rules are active. Active policy rules are those that are installed in a TCP/IP stack by the Policy Agent. A wide variety of attributes are available to specify time periods, and up to 25 time periods can be specified for any policy rule. The policy rule is active if any of the specified time intervals include the current time.

- Specify actions to take on behalf of traffic that maps to active policy rules, based on the evaluation of its conditions. QoS Actions contain a scope attribute that indicates the type of policy being defined, namely Differentiated Services, RSVP, or both Differentiated Services and RSVP. Up to four actions can be specified for each rule, but only one action per scope can be active at a time. IDS actions contain an action type that indicates the type of policy being defined, namely Attack, TR, Scan Global, or Scan Event. Only one IDS action can be specified for each rule. QoS and IDS actions (or conditions) can't be mixed within a single policy rule.

### Considerations for defining LDAP objects

LDAP objects can refer to other objects, using the DN of the referenced object. For example, a policy rule can be separated from its conditions and time periods, with those objects being referenced by the rule object.

Each LDAP object is composed of a number of attributes. Some of the attributes are generic LDAP attributes that apply to all LDAP objects. Other attributes are used only for Version 1 policy definitions. All other Version 2 and later policy attributes must begin with a unique prefix:

\[\text{ibm-}\]

When defining complex policy rules (those with more than one condition or action), two mutually exclusive methods can be used to associate the conditions or actions with the rule:

- The `ibm-policyConditionListDN` and `ibm-policyActionListDN` attributes can be omitted from the rule. In this case, the condition and action association objects MUST be created as subordinate objects to the policy rule, in other words, under the rule in the directory subtree. This is known as Directory Information Tree (DIT)-containment.

- The `ibm-policyConditionListDN` and `ibm-policyActionListDN` attributes can be specified in the rule. In this case, the condition and action association objects SHOULD be created as subordinate objects to the policy rule, in other words, under the rule in the directory subtree. However, this is not a requirement, only a recommendation. The objects can actually exist anywhere in the DIT.

### Policy Agent retrieval of LDAP objects

The design of the LDAP object tree should be carefully thought out. The Policy Agent uses a variety of mechanisms to search for and retrieve objects from an LDAP server:

- An initial search is done for a subtree of objects based on the `SearchBaseDN` parameter on the `ReadFromDirectory` statement.

- If any objects retrieved by this initial search contain subtree pointer references (using the `ibm-policySubtreesAuxContainedSet` attribute) then a search is done for all such subtrees. This is a recursive search: additional objects retrieved might also contain subtree pointer references.

- The above searches use a filter to retrieve only certain object classes. For LDAP protocol version 3, the default is to scan only for the `ibm-policy` object class. This is an abstract object class from which all other policy object classes are derived. Most LDAPv3 servers implement abstract and auxiliary classes such that this search will properly retrieve policy, and only policy, object classes. However, some LDAPv3 servers do not honor abstract/auxiliary object classes as a search filter. For these servers,
specify LDAP_AbstractPolicy NO on the ReadFromDirectory statement. This causes the searches to use a filter that retrieves ALL object classes.

- All of the above searches may be scoped, or filtered, using keywords specified on the ReadFromDirectory statement parameters SearchPolicyKeyword, SearchPolicyGroupKeyword, or SearchPolicyRuleKeyword. The LDAP server returns only objects with any matching keywords.

- Some objects retrieved using the above searches may contain DN pointer references to additional objects. These objects are individually retrieved. If the object to be retrieved is a policy rule, then a subtree search is performed, using the keywords specified on the ReadFromDirectory statement. All other objects are retrieved as single objects, using the DN pointers (no keywords are used on the search).

- All policy rule objects retrieved using the above searches are further filtered using the PolicyRole parameter on the ReadFromDirectory statement. Any rules that do not match policy roles specified on the ReadFromDirectory statement are discarded.

Therefore, it is possible to design an LDAP tree such that a minimal set of objects is initially retrieved, followed by many additional individual LDAP retrievals. If the total set of objects is large, there is a performance impact to retrieving objects in this manner. If possible, try to design the tree and the ReadFromDirectory parameters to retrieve the largest set of objects initially, to achieve the best performance, or to use subtree pointer references to retrieve larger sets of objects in one operation.

LDAP sample files

The following set of sample files provides an example of policy definitions in LDAP. For more information on using these sample files, see “Using the sample LDAP objects” on page 1358.

/usr/lpp/tcpip/samples/pagent.ldif
This file contains the top level directory structure for the set of sample quality of service (QoS) and intrusion detection services (IDS) policies.

/usr/lpp/tcpip/samples/pagent_starter_QOS.ldif
This file contains the starter set sample of LDAP definitions of QoS objects. This file requires the directory structure defined in sample file pagent.ldif.

/usr/lpp/tcpip/samples/pagent_starter_IDS.ldif
This file contains the starter set sample of LDAP definitions of IDS objects. This file requires the directory structure defined in sample file pagent.ldif.

/usr/lpp/tcpip/samples/pagent_advanced_QOS.ldif
This file contains the advanced set sample of LDAP definitions of QoS objects. This file requires the objects defined in the QoS starter set sample file pagent_starter_QOS.ldif and the directory structure defined in sample file pagent.ldif.

/usr/lpp/tcpip/samples/pagent_advanced_IDS.ldif
This file contains the advanced set sample of LDAP definitions of IDS objects. This file requires the objects defined in the IDS starter set sample file pagent_starter_IDS.ldif and the directory structure defined in sample file pagent.ldif.

The next set of samples is the definition of the schemas in LDAP protocol version 3 format. They must be installed on the LDAPv3 server in the correct order as an object in the server's database, rather than as configuration information. This process is known as schema publication. See RFCs 1804 and 2251. The files need to be specified on ldapmodify commands to modify the cn:schema entry in the server's database. See “Installing the schema definition on the LDAP server” on page 1358 for more information.

/usr/lpp/tcpip/samples/pagent_r8qosschema.ldif
This file contains the schema version 3 QoS schema definitions.

/usr/lpp/tcpip/samples/pagent_r5idsschema.ldif
This file contains the schema version 3 IDS schema definitions.

The next set of samples contain the text of draft documents used to develop the Version 3 schema.
This file contains the draft version of the proposed Policy Core Information Model (PCIM) used as the basis for the support in this release. PCIM is described by RFC 3060 but this file is an earlier draft level.

This file contains the draft version of the proposed Policy Core LDAP Schema Internet Draft used in z/OS V1R2 and later releases.

Note: This file is provided as-is and there are some differences between the draft and the implementation. The intent of this file is to provide background information on the level of the supported schema.

This file contains the draft version of the proposed Policy Conditions Internet Draft used in z/OS V1R2 and later releases.

Note: This file is provided as-is and there are some differences between the draft and the implementation. The intent of this file is to provide background information on the level of the supported schema.

Installing the schema definition on the LDAP server

The files that define the schema supported by the Policy Agent are shipped as a set of sample files. You need to modify the configuration of the LDAP server to include these schema definition files.

For LDAP protocol version 3, the schema definition is shipped in ldif format and installed on the LDAP server as a modification to the generic schema entry, known as a subschema. You must modify the existing schema entry to include the supported schema as a subschema by using the `ldapmodify` command. The schema definition files that you must install are located in the /usr/lpp/tcpip/samples directory. You must install the files in the following order:

1. pagent_r8qosschema.ldif
2. pagent_r5idsschema.ldif

This process is supported for the z/OS LDAP server.

To install the schema definitions, use commands like those shown in the following examples:

```
ldapmodify -h <server address> -p <server port> -D <administrator userid> -w <password> -f /usr/lpp/tcpip/samples/pagent_r8qosschema.ldif
```

```
ldapmodify -h <server address> -p <server port> -D <administrator userid> -w <password> -f /usr/lpp/tcpip/samples/pagent_r5idsschema.ldif
```

See the TDBM backend information in z/OS IBM Tivoli Directory Server Administration and Use for z/OS for more details.

Using the sample LDAP objects

There are 5 sample files that provide examples of policy definitions in LDAP:

- pagent.ldif
- pagent_starter_IDS.ldif
- pagent_starter_QOS.ldif
- pagent_advanced_IDS.ldif
- pagent_advanced_QOS.ldif

For brief descriptions of these files, see “Policy sample files” on page 773. You can either use some or all of these predefined policies in the starter and advanced sets, or modify them as needed.
The recommended way to create customized policies is to copy the sample policies you want to change to the custom portion of the pagent.ldif file (under the appropriate cn=custom root, QoS or IDS), modify them as needed, and then point to the custom set as the search base on the ReadFromDirectory statement.

For example, the pagent.ldif file has the following hierarchical structure [this shows the relevant parts of the Distinguished Name (DN) for each object]:

```
o=IBM, c=US (root object)
  cn=repository (root of all reusable policy conditions and actions)
  ou=policy (root of all policy groups and rules)
    cn=groups (root of sample groups)
    cn=starter (root of simple starter set of policies)
    cn=IDS (IDS starter set - actually defined in file pagent_starter_IDS.ldif)
    cn=QoS (QOS starter set - actually defined in file pagent_starter_QOS.ldif)
  cn=custom (root of customer-defined set of policies)
    cn=IDS (root of customer-defined IDS policies (empty))
    cn=QoS (root of customer-defined QOS policies (empty))
```

To obtain only the customized policies, specify the top custom policy group object as the search base on the ReadFromDirectory statement as follows:

```
ReadFromDirectory {
  ...
  SearchPolicyBaseDN   dn:cn=custom, ou=policy, o=IBM, c=US
  ...
}
```

**Note:** If your LDAP server has a root structure other than "o=IBM, c=US", be sure to change the root structure in all the files you want to use by replacing every instance of "o=IBM, c=US" with the appropriate root used on your LDAP server.

## Defining QoS policies using LDAP

This topic contains examples for defining QoS policies using LDAP.

### Differentiated Services policy example

The goal of this Differentiated Services policy is to map a subset of the traffic outbound from an FTP server.

This policy is identified as a Differentiated Services policy by the ibm-PolicyScope:DataTraffic attribute in the ibm-PolicyActionInstance object.

The following statements apply to the example in this topic:

- The policy rule selects traffic originated by ports in the range 20-21 (FTP outbound data connection uses port 20) from the source address 200.50.23.11 or 200.50.33.14 or 202::B055:1.
- The policy rule is active on weekdays between 6 a.m. and 10 p.m. local time, between the dates 7/1/2000 and 7/1/2005.
- The policy action specifies that the ToS byte be set to '10000000' for traffic that conforms to this policy.
The action establishes a token bucket traffic conditioner with a mean rate of 256 kilobits per second, a peak rate of 512 kilobits per second, and a burst size of 64 kilobytes. Any traffic that exceeds these specifications will be sent as best effort, with an accompanying ToS byte of '00000000'.

1360 z/OS Communications Server: IP Configuration Guide
Using an LDAP server for policy definitions
The goal of this policy is to ensure that outgoing data that match the specified attributes will be assigned a QoS service level defined in action "interactive1".

The following statements apply to the example in this topic:

- This rule will match only traffic on TCP connections (protocol 6) with a source port of 80 (i.e. HTTP server) and application defined data beginning with the string "/catalog".

- Because we are dealing with HTTP traffic, this rule is basically indicating that all outgoing traffic associated with a URI that begins with "/catalog" should be managed using the DS characteristics specified in the "interactive1" policy action.

RSVP policy example

The goal of this RSVP policy is to establish limits on resource reservations requested by RSVP applications using the RSVP API (RAPI) interface. The policy is identified as an RSVP policy by the ibm-PolicyScope:RSVP attribute in the ibm-PolicyActionInstance object.

The following statements apply to the example in this topic:

- The policy rule selects traffic from source ports in the range 8000 to 8001, with a protocol ID of 6 (TCP).
- One policy action specifies that the ToS byte be set to 01100000 for traffic that conforms to this policy.
- The RSVP policy action limits the type of RSVP service requested by RSVP applications to Controlled Load. Applications requesting Guaranteed service are downgraded to using Controlled Load service. In
addition, the action limits the mean rate and token bucket size to 50000 bytes per second and 6000 bytes, respectively. These values are requested by RSVP applications in the traffic specification, or Tspec.

- The action also limits the number of active RSVP flows that map to this policy to 10.

Sysplex distributor routing policy example

The goal of this sysplex distributor policy is to limit the number of SD target servers for inbound Telnet traffic. The policies are identified as SD policies by the ibm-policyGroupForLoadDistribution:TRUE attribute in the ibm-PolicyGroup object.

The following statements apply to the example in this topic:

- Separate policies are defined on the sysplex distributor distributing and target servers.
- The policy rules select incoming Telnet connection requests.
- The selected target server will be based on WLM information and QoS information if activated at the target servers.
- The rule (disttelnet) is coded on the distributing stack to select inbound traffic destined to the Telnet server.
- The rule (targtelnet) is coded on the target server to select outbound data from the Telnet server.
- If none of the specified target servers are available to service incoming requests (either the node is down or the Telnet server is not active), then sysplex distributor will distribute the requests to any available target server.

**Note:** If the ibm-Interface:1–0.0.0.0 attribute were not present, and none of the defined target servers were available, sysplex distributor would reject the request.

Appendix G. Related protocol specifications

This appendix lists the related protocol specifications (RFCs) for TCP/IP. The Internet Protocol suite is still evolving through requests for comments (RFC). New protocols are being designed and implemented by researchers and are brought to the attention of the Internet community in the form of RFCs. Some of these protocols are so useful that they become recommended protocols. That is, all future implementations for TCP/IP are recommended to implement these particular functions or protocols. These become the de facto standards, on which the TCP/IP protocol suite is built.

Draft RFCs that have been implemented in this and previous Communications Server releases are listed at the end of this topic.

Many features of TCP/IP Services are based on the following RFCs:

<table>
<thead>
<tr>
<th>RFC</th>
<th>Title and Author</th>

Internet drafts
Internet drafts are working documents of the Internet Engineering Task Force (IETF), its areas, and its working groups. Other groups can also distribute working documents as Internet drafts. You can see Internet drafts at http://www.ietf.org/ID.html.
Appendix H. Accessibility

Publications for this product are offered in Adobe Portable Document Format (PDF) and should be compliant with accessibility standards. If you experience difficulties when using PDF files, you can view the information through the z/OS Internet Library website http://www.ibm.com/systems/z/os/zos/library/bkserv/ or IBM Knowledge Center http://www.ibm.com/support/knowledgecenter/. If you continue to experience problems, send a message to Contact z/OS web page (www.ibm.com/systems/z/os/zos/websqs.html) or write to:

IBM Corporation
Attention: MHVRCFS Reader Comments
Department H6MA, Building 707
2455 South Road
Poughkeepsie, NY 12601-5400
USA

Accessibility features help a user who has a physical disability, such as restricted mobility or limited vision, to use software products successfully. The major accessibility features in z/OS enable users to:

- Use assistive technologies such as screen readers and screen magnifier software
- Operate specific or equivalent features using only the keyboard
- Customize display attributes such as color, contrast, and font size

Using assistive technologies

Assistive technology products, such as screen readers, function with the user interfaces found in z/OS. Consult the assistive technology documentation for specific information when using such products to access z/OS interfaces.

Keyboard navigation of the user interface

Users can access z/OS user interfaces using TSO/E or ISPF. See z/OS TSO/E Primer, z/OS TSO/E User’s Guide, and z/OS ISPF User’s Guide Vol I for information about accessing TSO/E and ISPF interfaces. These guides describe how to use TSO/E and ISPF, including the use of keyboard shortcuts or function keys (PF keys). Each guide includes the default settings for the PF keys and explains how to modify their functions.

z/OS information

One exception is command syntax that is published in railroad track format, which is accessible using screen readers with IBM Knowledge Center, as described in #accessibility/ddsd.

Dotted decimal syntax diagrams

Syntax diagrams are provided in dotted decimal format for users accessing IBM Knowledge Center using a screen reader. In dotted decimal format, each syntax element is written on a separate line. If two or more syntax elements are always present together (or always absent together), they can appear on the same line, because they can be considered as a single compound syntax element.
Each line starts with a dotted decimal number; for example, 3 or 3.1 or 3.1.1. To hear these numbers correctly, make sure that your screen reader is set to read out punctuation. All the syntax elements that have the same dotted decimal number (for example, all the syntax elements that have the number 3.1) are mutually exclusive alternatives. If you hear the lines 3.1 USERID and 3.1 SYSTEMID, you know that your syntax can include either USERID or SYSTEMID, but not both.

The dotted decimal numbering level denotes the level of nesting. For example, if a syntax element with dotted decimal number 3 is followed by a series of syntax elements with dotted decimal number 3.1, all the syntax elements numbered 3.1 are subordinate to the syntax element numbered 3.

Certain words and symbols are used next to the dotted decimal numbers to add information about the syntax elements. Occasionally, these words and symbols might occur at the beginning of the element itself. For ease of identification, if the word or symbol is a part of the syntax element, it is preceded by the backslash (\) character. The * symbol can be used next to a dotted decimal number to indicate that the syntax element repeats. For example, syntax element *FILE with dotted decimal number 3 is given the format 3 * FILE. Format 3* FILE indicates that syntax element FILE repeats. Format 3* \* FILE indicates that syntax element * FILE repeats.

Characters such as commas, which are used to separate a string of syntax elements, are shown in the syntax just before the items they separate. These characters can appear on the same line as each item, or on a separate line with the same dotted decimal number as the relevant items. The line can also show another symbol giving information about the syntax elements. For example, the lines 5.1*, 5.1 LASTRUN, and 5.1 DELETE mean that if you use more than one of the LASTRUN and DELETE syntax elements, the elements must be separated by a comma. If no separator is given, assume that you use a blank to separate each syntax element.

If a syntax element is preceded by the % symbol, this indicates a reference that is defined elsewhere. The string following the % symbol is the name of a syntax fragment rather than a literal. For example, the line 2.1 %OP1 means that you should see separate syntax fragment OP1.

The following words and symbols are used next to the dotted decimal numbers:

- A question mark (?) means an optional syntax element. A dotted decimal number followed by the ? symbol indicates that all the syntax elements with a corresponding dotted decimal number, and any subordinate syntax elements, are optional. If there is only one syntax element with a dotted decimal number, the ? symbol is displayed on the same line as the syntax element, (for example 5? NOTIFY). If there is more than one syntax element with a dotted decimal number, the ? symbol is displayed on a line by itself, followed by the syntax elements that are optional. For example, if you hear the lines 5 ?, 5 NOTIFY, and 5 UPDATE, you know that syntax elements NOTIFY and UPDATE are optional; that is, you can choose one or none of them. The ? symbol is equivalent to a bypass line in a railroad diagram.

- An exclamation mark (!) means a default syntax element. A dotted decimal number followed by the ! symbol and a syntax element indicate that the syntax element is the default option for all syntax elements that share the same dotted decimal number. Only one of the syntax elements that share the same dotted decimal number can specify a ! symbol. For example, if you hear the lines 2? FILE, 2.1! (KEEP), and 2.1 (DELETE), you know that (KEEP) is the default option for the FILE keyword. In this example, if you include the FILE keyword but do not specify an option, default option KEEP will be applied. A default option also applies to the next higher dotted decimal number. In this example, if the FILE keyword is omitted, default FILE(KEEP) is used. However, if you hear the lines 2? FILE, 2.1, 2.1.1! (KEEP), and 2.1.1 (DELETE), the default option KEEP applies only to the next higher dotted decimal number, 2.1 (which does not have an associated keyword), and does not apply to 2? FILE. Nothing is used if the keyword FILE is omitted.

- An asterisk (*) means a syntax element that can be repeated 0 or more times. A dotted decimal number followed by the * symbol indicates that this syntax element can be used zero or more times; that is, it is optional and can be repeated. For example, if you hear the line 5.1* data area, you know that you can include one data area, more than one data area, or no data area. If you hear the lines 3*, 3 HOST, and 3 STATE, you know that you can include HOST, STATE, both together, or nothing.

Notes:

1. If a dotted decimal number has an asterisk (*) next to it and there is only one item with that dotted decimal number, you can repeat that same item more than once.
2. If a dotted decimal number has an asterisk next to it and several items have that dotted decimal number, you can use more than one item from the list, but you cannot use the items more than once each. In the previous example, you could write HOST STATE, but you could not write HOST HOST.

3. The * symbol is equivalent to a loop-back line in a railroad syntax diagram.

• + means a syntax element that must be included one or more times. A dotted decimal number followed by the + symbol indicates that this syntax element must be included one or more times; that is, it must be included at least once and can be repeated. For example, if you hear the line 6.1+ data area, you must include at least one data area. If you hear the lines 2+, 2 HOST, and 2 STATE, you know that you must include HOST, STATE, or both. Similar to the * symbol, the + symbol can only repeat a particular item if it is the only item with that dotted decimal number. The + symbol, like the * symbol, is equivalent to a loop-back line in a railroad syntax diagram.
Notices

This information was developed for products and services that are offered in the USA or elsewhere. IBM may not offer the products, services, or features discussed in this document in other countries. Consult your local IBM representative for information on the products and services currently available in your area. Any reference to an IBM product, program, or service is not intended to state or imply that only that IBM product, program, or service may be used. Any functionally equivalent product, program, or service that does not infringe any IBM intellectual property right may be used instead. However, it is the user’s responsibility to evaluate and verify the operation of any non-IBM product, program, or service.

IBM may have patents or pending patent applications covering subject matter described in this document. The furnishing of this document does not grant you any license to these patents. You can send license inquiries, in writing, to:

IBM Director of Licensing IBM Corporation North Castle Drive, MD-NC119 Armonk, NY 10504-1785 United States of America

For license inquiries regarding double-byte character set (DBCS) information, contact the IBM Intellectual Property Department in your country or send inquiries, in writing, to:

This information contains examples of data and reports used in daily business operations. To illustrate them as completely as possible, the examples include the names of individuals, companies, brands, and products. All of these names are fictitious and any similarity to the names and addresses used by an actual business enterprise is entirely coincidental.

COPYRIGHT LICENSE:

This information contains sample application programs in source language, which illustrate programming techniques on various operating platforms. You may copy, modify, and distribute these sample programs in any form without payment to IBM, for the purposes of developing, using, marketing or distributing application programs conforming to the application programming interface for the operating platform for which the sample programs are written. These examples have not been thoroughly tested under all conditions. IBM, therefore, cannot guarantee or imply reliability, serviceability, or function of these programs. The sample programs are provided "AS IS", without warranty of any kind. IBM shall not be liable for any damages arising out of your use of the sample programs.

Terms and conditions for product documentation

Permissions for the use of these publications are granted subject to the following terms and conditions.

Applicability
These terms and conditions are in addition to any terms of use for the IBM website.

Personal use
You may reproduce these publications for your personal, noncommercial use provided that all proprietary notices are preserved. You may not distribute, display or make derivative work of these publications, or any portion thereof, without the express consent of IBM.

Commercial use
You may reproduce, distribute and display these publications solely within your enterprise provided that all proprietary notices are preserved. You may not make derivative works of these publications, or reproduce, distribute or display these publications or any portion thereof outside your enterprise, without the express consent of IBM.

Rights
Except as expressly granted in this permission, no other permissions, licenses or rights are granted, either express or implied, to the publications or any information, data, software or other intellectual property contained therein.
IBM reserves the right to withdraw the permissions granted herein whenever, in its discretion, the use of the publications is detrimental to its interest or, as determined by IBM, the above instructions are not being properly followed.

You may not download, export or re-export this information except in full compliance with all applicable laws and regulations, including all United States export laws and regulations.

IBM Online Privacy Statement

IBM Software products, including software as a service solutions, ("Software Offerings") may use cookies or other technologies to collect product usage information, to help improve the end user experience, to tailor interactions with the end user, or for other purposes. In many cases no personally identifiable information is collected by the Software Offerings. Some of our Software Offerings can help enable you to collect personally identifiable information. If this Software Offering uses cookies to collect personally identifiable information, specific information about this offering's use of cookies is set forth below.

Depending upon the configurations deployed, this Software Offering may use session cookies that collect each user’s name, email address, phone number, or other personally identifiable information for purposes of enhanced user usability and single sign-on configuration. These cookies can be disabled, but disabling them will also eliminate the functionality they enable.

If the configurations deployed for this Software Offering provide you as customer the ability to collect personally identifiable information from end users via cookies and other technologies, you should seek your own legal advice about any laws applicable to such data collection, including any requirements for notice and consent.

For more information about the use of various technologies, including cookies, for these purposes, see IBM’s Privacy Policy at ibm.com/privacy and IBM’s Online Privacy Statement at ibm.com/privacy/details in the section entitled “Cookies, Web Beacons and Other Technologies,” and the “IBM Software Products and Software-as-a-Service Privacy Statement” at ibm.com/software/info/product-privacy.

Policy for unsupported hardware

Various z/OS elements, such as DFSMS, JES2, JES3, and MVS, contain code that supports specific hardware servers or devices. In some cases, this device-related element support remains in the product even after the hardware devices pass their announced End of Service date. z/OS may continue to service element code; however, it will not provide service related to unsupported hardware devices. Software problems related to these devices will not be accepted for service, and current service activity will cease if a problem is determined to be associated with out-of-support devices. In such cases, fixes will not be issued.

Minimum supported hardware

The minimum supported hardware for z/OS releases identified in z/OS announcements can subsequently change when service for particular servers or devices is withdrawn. Likewise, the levels of other software products supported on a particular release of z/OS are subject to the service support lifecycle of those products. Therefore, z/OS and its product publications (for example, panels, samples, messages, and product documentation) can include references to hardware and software that is no longer supported.

• For information about software support lifecycle, see: IBM Lifecycle Support for z/OS (www.ibm.com/software/support/systemsz/lifecycle)

• For information about currently-supported IBM hardware, contact your IBM representative.
Policy for unsupported hardware

Various z/OS elements, such as DFSMS, HCD, JES2, JES3, and MVS, contain code that supports specific hardware servers or devices. In some cases, this device-related element support remains in the product even after the hardware devices pass their announced End of Service date. z/OS may continue to service element code; however, it will not provide service related to unsupported hardware devices. Software problems related to these devices will not be accepted for service, and current service activity will cease if a problem is determined to be associated with out-of-support devices. In such cases, fixes will not be issued.

Trademarks

IBM, the IBM logo, and ibm.com are trademarks or registered trademarks of International Business Machines Corp., registered in many jurisdictions worldwide. Other product and service names might be trademarks of IBM or other companies. A current list of IBM trademarks is available on the web at Copyright and trademark information at www.ibm.com/legal/copytrade.shtml.
This bibliography contains descriptions of the documents in the z/OS Communications Server library. z/OS Communications Server documentation is available online at the z/OS Internet Library web page at http://www.ibm.com/systems/z/os/zos/library/bkserv/.

### z/OS Communications Server library updates

Updates to documents are also available on RETAIN and in information APARs (info APARs). Go to [http://www.software.ibm.com/support](http://www.software.ibm.com/support) to view information APARs.

### z/OS Communications Server information

z/OS Communications Server product information is grouped by task in the following tables.

#### Planning

<table>
<thead>
<tr>
<th>Title</th>
<th>Number</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>z/OS Communications Server: New Function Summary</td>
<td>GC27-3664</td>
<td>This document is intended to help you plan for new IP or SNA functions, whether you are migrating from a previous version or installing z/OS for the first time. It summarizes what is new in the release and identifies the suggested and required modifications needed to use the enhanced functions.</td>
</tr>
<tr>
<td>z/OS Communications Server: IPv6 Network and Application Design Guide</td>
<td>SC27-3663</td>
<td>This document is a high-level introduction to IPv6. It describes concepts of z/OS Communications Server's support of IPv6, coexistence with IPv4, and migration issues.</td>
</tr>
</tbody>
</table>

#### Resource definition, configuration, and tuning

<table>
<thead>
<tr>
<th>Title</th>
<th>Number</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>z/OS Communications Server: IP Configuration Guide</td>
<td>SC27-3650</td>
<td>This document describes the major concepts involved in understanding and configuring an IP network. Familiarity with the z/OS operating system, IP protocols, z/OS UNIX System Services, and IBM Time Sharing Option (TSO) is recommended. Use this document with the z/OS Communications Server: IP Configuration Reference.</td>
</tr>
</tbody>
</table>
### Title | Number | Description
---|---|---
**z/OS Communications Server:** IP Configuration Reference | SC27-3651 | This document presents information for people who want to administer and maintain IP. Use this document with the z/OS Communications Server: IP Configuration Guide. The information in this document includes:
- TCP/IP configuration data sets
- Configuration statements
- Translation tables
- Protocol number and port assignments

**z/OS Communications Server:** SNA Network Implementation Guide | SC27-3672 | This document presents the major concepts involved in implementing an SNA network. Use this document with the z/OS Communications Server: SNA Resource Definition Reference.

**z/OS Communications Server:** SNA Resource Definition Reference | SC27-3675 | This document describes each SNA definition statement, start option, and macroinstruction for user tables. It also describes NCP definition statements that affect SNA. Use this document with the z/OS Communications Server: SNA Network Implementation Guide.

**z/OS Communications Server:** SNA Resource Definition Samples | SC27-3676 | This document contains sample definitions to help you implement SNA functions in your networks, and includes sample major node definitions.

**z/OS Communications Server:** IP Network Print Facility | SC27-3658 | This document is for systems programmers and network administrators who need to prepare their network to route SNA, JES2, or JES3 printer output to remote printers using TCP/IP Services.

### Operation

### Title | Number | Description
---|---|---
**z/OS Communications Server:** IP User's Guide and Commands | SC27-3662 | This document describes how to use TCP/IP applications. It contains requests with which a user can log on to a remote host using Telnet, transfer data sets using FTP, send electronic mail, print on remote printers, and authenticate network users.

**z/OS Communications Server:** IP System Administrator's Commands | SC27-3661 | This document describes the functions and commands helpful in configuring or monitoring your system. It contains system administrator's commands, such as TSO NETSTAT, PING, TRACERTE and their UNIX counterparts. It also includes TSO and MVS commands commonly used during the IP configuration process.

**z/OS Communications Server:** SNA Operation | SC27-3673 | This document serves as a reference for programmers and operators requiring detailed information about specific operator commands.

**z/OS Communications Server:** Quick Reference | SC27-3665 | This document contains essential information about SNA and IP commands.
### Customization

<table>
<thead>
<tr>
<th>Title</th>
<th>Number</th>
<th>Description</th>
</tr>
</thead>
</table>
| z/OS Communications Server: SNA Customization | SC27-3666 | This document enables you to customize SNA, and includes the following information:  
  - Communication network management (CNM) routing table
  - Logon-interpret routine requirements
  - Logon manager installation-wide exit routine for the CLU search exit
  - TSO/SNA installation-wide exit routines
  - SNA installation-wide exit routines |

### Writing application programs

<table>
<thead>
<tr>
<th>Title</th>
<th>Number</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>z/OS Communications Server: IP Sockets Application Programming Interface Guide and Reference</td>
<td>SC27-3660</td>
<td>This document describes the syntax and semantics of program source code necessary to write your own application programming interface (API) into TCP/IP. You can use this interface as the communication base for writing your own client or server application. You can also use this document to adapt your existing applications to communicate with each other using sockets over TCP/IP.</td>
</tr>
<tr>
<td>z/OS Communications Server: IP CICS Sockets Guide</td>
<td>SC27-3649</td>
<td>This document is for programmers who want to set up, write application programs for, and diagnose problems with the socket interface for CICS using z/OS TCP/IP.</td>
</tr>
<tr>
<td>z/OS Communications Server: IP IMS Sockets Guide</td>
<td>SC27-3653</td>
<td>This document is for programmers who want application programs that use the IMS TCP/IP application development services provided by the TCP/IP Services of IBM.</td>
</tr>
<tr>
<td>z/OS Communications Server: IP Programmer’s Guide and Reference</td>
<td>SC27-3659</td>
<td>This document describes the syntax and semantics of a set of high-level application functions that you can use to program your own applications in a TCP/IP environment. These functions provide support for application facilities, such as user authentication, distributed databases, distributed processing, network management, and device sharing. Familiarity with the z/OS operating system, TCP/IP protocols, and IBM Time Sharing Option (TSO) is recommended.</td>
</tr>
<tr>
<td>z/OS Communications Server: SNA Programming</td>
<td>SC27-3674</td>
<td>This document describes how to use SNA macroinstructions to send data to and receive data from (1) a terminal in either the same or a different domain, or (2) another application program in either the same or a different domain.</td>
</tr>
<tr>
<td>z/OS Communications Server: SNA Programmer’s LU 6.2 Guide</td>
<td>SC27-3669</td>
<td>This document describes how to use the SNA LU 6.2 application programming interface for host application programs. This document applies to programs that use only LU 6.2 sessions or that use LU 6.2 sessions along with other session types. (Only LU 6.2 sessions are covered in this document.)</td>
</tr>
<tr>
<td>Title</td>
<td>Number</td>
<td>Description</td>
</tr>
<tr>
<td>-------</td>
<td>--------</td>
<td>-------------</td>
</tr>
<tr>
<td>z/OS Communications Server: SNA Programmer’s LU 6.2 Reference</td>
<td>SC27-3670</td>
<td>This document provides reference material for the SNA LU 6.2 programming interface for host application programs.</td>
</tr>
<tr>
<td>z/OS Communications Server: CSM Guide</td>
<td>SC27-3647</td>
<td>This document describes how applications use the communications storage manager.</td>
</tr>
</tbody>
</table>

### Diagnosis

<table>
<thead>
<tr>
<th>Title</th>
<th>Number</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>z/OS Communications Server: IP Diagnosis Guide</td>
<td>GC27-3652</td>
<td>This document explains how to diagnose TCP/IP problems and how to determine whether a specific problem is in the TCP/IP product code. It explains how to gather information for and describe problems to the IBM Software Support Center.</td>
</tr>
<tr>
<td>z/OS Communications Server: ACF/TAP Trace Analysis Handbook</td>
<td>GC27-3645</td>
<td>This document explains how to gather the trace data that is collected and stored in the host processor. It also explains how to use the Advanced Communications Function/Trace Analysis Program (ACF/TAP) service aid to produce reports for analyzing the trace data information.</td>
</tr>
<tr>
<td>z/OS Communications Server: SNA Diagnosis Vol 1, Techniques and Procedures and z/OS Communications Server: SNA Diagnosis Vol 2, FFST Dumps and the VIT</td>
<td>GC27-3667 GC27-3668</td>
<td>These documents help you identify an SNA problem, classify it, and collect information about it before you call the IBM Support Center. The information collected includes traces, dumps, and other problem documentation.</td>
</tr>
<tr>
<td>z/OS Communications Server: SNA Data Areas Volume 1 and z/OS Communications Server: SNA Data Areas Volume 2</td>
<td>GC31-6852 GC31-6853</td>
<td>These documents describe SNA data areas and can be used to read an SNA dump. They are intended for IBM programming service representatives and customer personnel who are diagnosing problems with SNA.</td>
</tr>
</tbody>
</table>

### Messages and codes

<table>
<thead>
<tr>
<th>Title</th>
<th>Number</th>
<th>Description</th>
</tr>
</thead>
</table>
| z/OS Communications Server: SNA Messages | SC27-3671 | This document describes the ELM, IKT, IST, IUT, IVT, and USS messages. Other information in this document includes:  
  • Command and RU types in SNA messages  
  • Node and ID types in SNA messages  
  • Supplemental message-related information |
<table>
<thead>
<tr>
<th>Title</th>
<th>Number</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>z/OS Communications Server: IP Messages Volume 1 (EZA)</td>
<td>SC27-3654</td>
<td>This volume contains TCP/IP messages beginning with EZA.</td>
</tr>
<tr>
<td>z/OS Communications Server: IP Messages Volume 2 (EZB, EZD)</td>
<td>SC27-3655</td>
<td>This volume contains TCP/IP messages beginning with EZB or EZD.</td>
</tr>
<tr>
<td>z/OS Communications Server: IP Messages Volume 3 (EZY)</td>
<td>SC27-3656</td>
<td>This volume contains TCP/IP messages beginning with EZY.</td>
</tr>
<tr>
<td>z/OS Communications Server: IP Messages Volume 4 (EZZ, SNM)</td>
<td>SC27-3657</td>
<td>This volume contains TCP/IP messages beginning with EZZ and SNM.</td>
</tr>
<tr>
<td>z/OS Communications Server: IP and SNA Codes</td>
<td>SC27-3648</td>
<td>This document describes codes and other information that appear in z/OS Communications Server messages.</td>
</tr>
